From the *Center for Laboratories and Research, New York State Department of Health, Albany, and the †Department of Microbiology, State University of New York, Buffalo, New York, USA

SUMMARY Groups of 10 young male guinea pigs of inbred strains 2 and 13 and outbred strains Hartley A, Hartley B, and one deficient in the fourth component of complement (C4D) were infected intradermally with 80 × 10⁶ *Treponema pallidum* (Nichols). The course of infection and production of antitreponemal antibody were examined. Strain C4D guinea pigs were the most susceptible to infection (100%); inbred strains 2 and 13 and outbred strain Hartley B showed 80-90% symptomatic infection; and the Hartley A strain was the least susceptible to infection (10%). Strain 13 animals responded with the highest antitreponemal antibody activity, and the Hartley A strain with the lowest. The results suggest that genetic factors or complement, or both, may influence the degree of susceptibility to infection with *T. pallidum* in guinea pigs.

Introduction

Neither clinical investigations in man nor experimental studies in the rabbit have provided complete information on the nature of syphilis. The guinea pig, because it is less susceptible to infection with *Treponema pallidum* than the rabbit, has been neglected as an experimental model. Yet studies with this animal could be important for exploration of the immunopathological mechanisms of the disease.¹ ²

The median infectious dose (ID₃₀) for outbred guinea pigs is about 0·1 × 10⁶ organisms,¹ and similar results have been obtained with inbred strains 2 and 13.³ Pierce et al showed that when young male Hartley guinea pigs were infected with proper concentrations of *T. pallidum* (Nichols) they responded with dark field positive lesions, production of treponemal IgG antibody, and histopathological changes in the lymph nodes and spleen.¹ The animals did not produce treponemal IgM⁴ or cardiolipin antibodies.¹ ²

In anticipation of using this animal model for studies of the genetic factors influencing susceptibility to infection and the course of the disease and of the role of complement in syphilis, we examined five species of guinea pigs differing in genetic make up and complement activity. These strains were tested for their susceptibility to infection with *T. pallidum*, and the course of infection was monitored. We report here that the strains differed appreciably in their susceptibility to infection with *T. pallidum* (Nichols).

Materials and methods

ANIMALS

Inbred and outbred strains of guinea pigs were used in the study. Animals of inbred strains 2 and 13 were bought by our centre's animal production facility (Griffin Laboratory) from the National Institutes of Health (NIH) in the 1970s and have since been reared as a line bred colony. Outbred Hartley guinea pigs (Hartley A) have been reared in our institution as a closed colony since 1917. The colony was started by Caesarean section and bred at random. Brothers and sisters were mated during 1954-68, after which random breeding was resumed. Another Hartley strain (Hartley B), (bought from Buckberg Animal Farm, Tompkins Cove, New York, USA) is the strain used in previous studies.¹ ² A strain deficient in the fourth component of complement (C4D), which was discovered and established at NIH,¹ ² was obtained by Griffin Laboratory in 1975 and has since been bred at random.

All animals were male, weighed 300-400 g, and were housed individually in air conditioned quarters.

Accepted for publication 21 June 1984
(18-22°C) and fed food free of antibiotics and water ad libitum.

INFECTION

*T. pallidum* (Nichols) was obtained from the testes of infected Nys Flemish Giant (FG) rabbits killed with euthanasia agent T-61 (American Hoechst) at the peak of orchitis (10 days). The organisms were extracted into phosphate buffered saline (PBS) pH 7.2 and counted. All 50 guinea pigs (groups of 10 animals of each strain) were depilated and infected intradermally under general anaesthesia (Ketaset; Bristol Laboratories, Syracuse, New York, USA) with 80 × 10⁶ organisms. During inoculation (about two hours for the 50 animals) the treponemal suspension was kept at room temperature and stirred. Single animals were selected alternately from the five groups for infection. The animals were examined daily for lesions, and blood was collected to measure antibody at regular intervals from day 17 of infection.

**FLUORESCENT TREPONEMAL ANTIBODY TEST**

Heat inactivated serum samples were initially diluted (1:5) in a sorbent, and further dilutions were made in PBS. Serum samples were applied to commercially prepared Treposlides (Beckman Instruments) and incubated in a humidified chamber at 37°C for 30 minutes. After washing in PBS, appropriately diluted fluorescein isothiocyanate conjugated rabbit antiserum to guinea pig IgG was applied to the slides, and they were reincubated for 30 minutes at 37°C. After another washing the slides were dried, mounted, and examined under a Nikkon Optiphot microscope equipped with interference filters, xenon illumination, and 10 × ocular and 40 × dry objective lenses. The end point titre was the last dilution to give 1+ reactivity.

**CARDIOLIPIIN ANTIBODIES**

Selected serum samples from all five strains were examined for cardiolipin antibodies by the Venereal Disease Research Laboratory (VDRL) test.

**RESULTS**

Table I summarises the course of infection and antibody response. For six days no change was seen at the site of infection, excluding the possibility of a contaminated inoculum. On day 7 an erythematous area of about 5 mm in diameter was seen in most animals. In time it developed (except in the Hartley A strain) to a definite induration, which exceeded 15 mm in diameter in some animals of the C4D strain. Table II shows the size and course of lesions in six C4D animals.

Central necrosis occurred in almost all lesions, especially during the regression phase, which varied in different animals. Figures 1 and 2 show lesions in animals of four strains. The duration of the lesions varied: it was longest (21 to 60 days) in the C4D animals and shortest (five days) in the single Hartley A animal. The percentage of symptomatic infection was also highest (100%) in the C4D guinea pigs and lowest (10%) in the Hartley A. Dermal lesions were examined by dark field microscopy in at least three animals of each group except Hartley A. All lesions contained motile *T. pallidum* micro-organisms, which appeared to be slightly more slender than those from rabbit cutaneous fluid. During the course of infection the animals did not have raised temperatures, and their increase in body weight was similar to that of control non-infected animals of corresponding age.

*Lesions of four of 10 animals were used for dark field examination and are not included here.
Differences in susceptibility to infection with *T. pallidum* (Nichols) between five strains of guinea pig

The regional lymph nodes were not enlarged on palpation.

Blood samples were taken from all animals on day 17 after infection and tested for antitreponemal antibodies (table I). Four animals from each group with detectable antibodies were selected for quantitative serological studies (tables I and III). The maximum titre in individual animals was reached by day 30 in the Hartley A strain and by day 90 in strains 2 and Hartley B. The highest group mean titres were found in the inbred strains 13 and 2, and the lowest in Hartley A. Antibody persisted for long periods in representative animals of each strain examined for seven months. In some instances (animals 5, 18, 22, and 43) the antibody fluctuated, suggesting a continuous but variable antigenic stimulus. Serum samples examined for cardiolipin antibodies gave negative results, which confirmed our earlier results with outbred guinea pigs.¹ ²

Discussion

During the past few years research on experimental syphilis has been leaning more towards molecular description of *T. pallidum* and recombinant DNA. Though newer technology may offer more excitement and is theoretically very promising, we may have to wait a long time for the practical results of these approaches. Meanwhile syphilis maintains an unhealthy fluctuation of incidence and remains high on the list of notifiable venereal diseases (third in the...

United States of America. All efforts should be made to learn more about this disease.

The rabbit has not yet been exhausted as a model for syphilis, but it has serious limitations. One is the difficulty of dissecting the specific from the non-specific responses because the rabbit produces both cardiolipin antibodies and antibodies to various non-pathogenic treponemes. Another is that in rabbits the T. pallidum micro-organisms hide in an envelope of rabbit proteins, thus presenting a difficult target.
for the host immune mechanism. The guinea pig, on
the other hand, produces only antitreponemal IgG
antibodies, which are not affected by absorption
with intact T. phagedenis biotype Reiter (Pierce CS,
Wicher K, unpublished observation), and it mounts a
specific T cell response to T. pallidum. This animal
thus lends itself to studies of immune responses, as
well as of genetic factors of the host’s susceptibility
to disease.

Our results with Hartley B guinea pigs confirmed
the percentage (87.5%) of symptomatic infections
previously reported in these animals. In contrast, the
outbred Hartley A animals, which have been reared
in our laboratory as a closed colony since 1917,
showed a pronounced resistance to infection. The
susceptibility of the inbred strains 2 and 13 was
similar to that of Hartley B. The C4D animals were
the most susceptible and produced the largest lesions,
which lasted for two months. Whether the heightened
susceptibility of this strain to syphilitic infection is
due to the lack of C4 alone or to other genetic
characteristics as well has still to be clarified.

Complement activity (total haemolytic activity)
(192 to 215 U/ml) was identical in age matched non-
infected guinea pigs of strains 2 and Hartley A.
Serum samples from non-infected C4D guinea pigs
had no detectable haemolytic activity (<10 U/ml).
The lack of susceptibility to infection in the Hartley
A animals may therefore not be attributable to their
high complement activity. In the C4D animals,
however, the severity and duration of infection may
be related to complement. This strain has defects in
a number of immunological functions, such as
diminished opsonic and bactericidal activity, which
require sequential activation of early components in
the classic pathway.

As previously described, the humoral response in
all five strains was restricted to production of anti-
treponemal antibodies, with a total lack of anti-
cardiolipin antibodies. It is generally assumed that
cardiolipin antibodies in an infected host reflect
tissue damage and are therefore not produced in
animal species with little or no susceptibility to
infection. Our results do not support this assumption,
however, as neither resistant (Hartley A) nor highly
susceptible (C4D) animals produced anti-
cardiolipin antibodies. For reasons at present
unknown, lipids do not seem to be immunogenic for
the guinea pig. Several protocols of immunisation
used previously by Pierce with susceptible Hartley B
guinea pigs failed to produce antibodies to lipids. By
using immune complexes consisting of rabbit cardio-
lipin antibodies and VDRL antigen we were recently
able to obtain a very low titre of antibodies reacting
with VDRL antigen, but this was achieved in only
one of 10 Hartley A guinea pigs after 10 intradermal
injections. A rabbit used as a control had a higher
antiacardiolipin titre after three injections (Wicher V,
Wicher K, unpublished observation). The resistance
of guinea pigs to the production of cardiolipin anti-
bodies is a welcome characteristic, as in experimental
infection with T. pallidum the animals mount an
immune response to the causative organism only.

Our previous studies and that reported here
provide supportive evidence that the guinea pig is a
useful model for the investigation of syphilis. This
animal offers the opportunity to study, not only
specific immune responses, but also genetic factors
