Vaginitis emphysematosa

Vaginitis emphysematosa is usually a self limited cystic disorder of the vagina. The paucity of reports on this rare entity and the fact that it can first present to the sexually transmitted diseases (STD) clinic where, for want of a better diagnosis, it may be passed off as condyloma acuminatum, prompted us to document the condition in a young woman.

**Case report**

A 29 year old gravida 8, para 8 woman presented with an asymptomatic growth in the vaginal introitus of 2 years’ duration. It had started spontaneously, gradually attained the size of a small lemon, and had remained as such for months. On examination she was of average build and nutrition without any associated disorders like diabetes and hypertension. Local examination revealed a pedunculated mass measuring 2 cm in diameter protruding from the right side of the labia minora. There was no discharge and no other abnormality was visualised. The regional lymph nodes were not enlarged. Systemic examination revealed no abnormality. Routine blood tests, including VDRL and urinalysis were within normal limits. The lesion was excised with a provisional diagnosis of condyloma acuminatum and sent for histopathology. Light microscopic examination revealed a normal vaginal epithelium. The lamina propria contained multiple cysts of varying sizes (fig 1). The cysts were lined by a single layer of cuboidal cells. Most of the cysts were empty except for scantly hyaline material in some of the larger ones. In between the cysts were lymphohistiocytic infiltrates. Few scattered plasma cells were seen but there were no granulomas or giant cells.

**Comment**

Vaginitis emphysematosa is not only a rare condition but it is seldom diagnosed on examination as it lacks specific features to arouse clinical suspicion. Hence it has often been the histopathologist or the radiologist who hints at the possibility of vaginitis emphysematosa. In an exhaustive review of the English literature the salient features brought out include the occurrence of vaginitis emphysematosa in a wide age range after menarche to well beyond menopause, frequent association with pregnancy and at times cardiopulmonary disease, and involvement of the lamina propria of the upper vagina, extending at times to the lower vagina, the cervix, and rarely the vulva. The main interest in vaginitis emphysematosa has been the histopathological presence of empty cavities in the lesions containing gas similar to atmospheric air with a high concentration of carbon dioxide. How exactly these gases are produced is not clear. Some attribute this to associated trichomonal or Gardnerella infection, the cure of which resulted in apparent subsidence of vaginitis emphysematosa. Immunosuppression as a predisposing factor leading to the development of vaginitis emphysematosa has also been suggested.

Our patient presented with a lesion at the lower end of the vagina that was initially diagnosed as condyloma acuminata. She was not pregnant and had no associated vaginal infection, cardiac disease, or evidence of immunosuppression. Mild inflammatory signs were seen in our patient. Though the term "vaginitis" has been employed it has been observed that inflammation is generally mild or absent. This may also account for the lack of symptoms in most of these patients. The natural course for vaginitis emphysematosa is to resolve spontaneously and in most patients this has been an accidental finding. On those occasions when the mass makes the patients seek advice simple excision may be done as in the present case. Apart from solid tumours like condyloma acuminata, other benign cystic lesions of the vagina like inclusion cyst, Gartner duct cysts, and endometriosis should be considered in the differential diagnosis.

**Management of screened chlamydia positive women**

Evidence based and minimally harmful management of screened positive people is an essential component of any screening programme.

In the pilot chlamydia programme the protocol for those who screened positive included testing for other genital infections. This may also account for the lack of symptoms in most of these patients. The natural course for vaginitis emphysematosa is to resolve spontaneously and in most patients this has been an accidental finding. On those occasions when the mass makes the patients seek advice simple excision may be done as in the present case. Apart from solid tumours like condyloma acuminata, other benign cystic lesions of the vagina like inclusion cyst, Gartner duct cysts, and endometriosis should be considered in the differential diagnosis.

**Management of screened chlamydia positive women**

Evidence based and minimally harmful management of screened positive people is an essential component of any screening programme.

In the pilot chlamydia programme the protocol for those who screened positive included testing for other genital infections. Evidence based and minimally harmful management of screened positive people is an essential component of any screening programme.

In the pilot chlamydia programme the protocol for those who screened positive included testing for other genital infections. These avoid disparate management and had the added benefit of removing the “screening” test in GUM and most returned there for management.
transmitted infections in these women comprised three cases of gonorrhoea, 30 of genital warts, and six of herpes simplex. There were also 11 cases of candida and 18 of bacterial vaginosis. These figures represent multiple infections for several women.

Four hundred and six women screened in other healthcare settings tested chlamydia positive. The community health advisers treated 321 of these and 85 agreed to attend GUM. Five of these women (5.8%) had another sexually transmitted infection comprising only one case of gonorrhoea, two cases of genital warts, and two cases of genital herpes. There were also nine cases of candida and 17 of bacterial vaginosis.

If efficient and effective treatment for chlamydia is to take place in the community then health advisers will be essential as in the Wirral pilot scheme. They will need to establish in each case whether there are symptoms or special risk factors that transform the process from screening to one of diagnosis. Although diagnosis should involve testing for all relevant causes of the symptoms, we have found no evidence to support this as routine in a screening programme if it is known that the community prevalence of other significant infections is low. The invasive nature and possible stigmatisation by seeking for other infections together with the cost to individuals and the health service could be balanced against any personal or community benefits from the strategy.

The women who chose to be treated in the community clinics—a focus for accurate sexual health care. Br J Fam Plann 1999;24:160-3.

Key messages

1 Bacterial co-infection of chlamydia diagnosed during screening outside STI clinic settings is low

2 Routine diagnostic testing should only be reserved for those symptomatic or with special risk

3 Testing of the original urine sample for gonorrhoea is an acceptable alternative
