MULTI-ANTIGEN SEQUENCE TYPES (NG-MAST) AND ANTIMICROBIAL SUSCEPTIBILITIES ON NEISSERIA GONORRHOEAE ISOLATED IN CANADA, 2010–2011

I Martin,1 P Sawatzky,2 G Liu,3 V Allen,4 L Hoang,5 L Lefebvre,6 M Lovgren,1 T Wong,1 The Canadian Public Health Laboratory Network.1 Public Health Agency of Canada, National Microbiology Laboratory, Winnipeg, MB, Canada;2 Public Health Ontario Laboratories, Toronto, ON, Canada;3 British Columbia Centre for Disease Control, Vancouver, BC, Canada;4 Laboratoire de santé publique du Québec, Ste-Anne-de-Bellevue, QC, Canada;5 Provincial Laboratory for Public Health Alberta, Edmonton, AB, Canada;6 Public Health Agency of Canada, Ottawa, ON, Canada

Background Neisseria gonorrhoeae have acquired resistance to many antibiotics and have developed decreasing susceptibilities to 3rd generation cephalosporins.

Method NG-MAST sequence types and minimum inhibitory concentration (MICs) by agar dilution were determined for each N. gonorrhoeae isolate collected by Canadian provincial public health laboratories and submitted to the National Microbiology Laboratory between 2010–2011 (N = 2391). Isolates are submitted to the NML only when the provincial laboratories identify resistance to at least one antibiotic or if the provincial laboratories do not conduct any antimicrobial susceptibility testing. MIC interpretations were based on the criteria of the Clinical Laboratory Standards Institute (CLSI) and the World Health Organization (WHO) criteria for decreased susceptibility to cephaplatin.

Results Among all the isolates tested in Canada during 2010–2011, 23.5% (1489/6330) were resistant to penicillin, 31.8% (2014/6330) to tetracycline, 28.9% (1828/6330) to erythromycin, 32.4% (2051/6330) to ciprofloxacin and 0.8% (50/6330) to azithromycin. Based on the WHO guidelines for decreased susceptibility to cefixime MIC ≥ 0.25 mg/L and decreased susceptibility to ceftriaxone MIC ≥ 0.125 mg/L, 3.8% (98/2970) of isolates had decreased susceptibility to cefixime in 2010. This number rose to 4.2% (140/3360) in 2011. Ceftriaxone MICs decreased slightly from 7.2% (210/2970) of isolates with decreased susceptibility in 2010 to 6.2% (208/3360) isolates with decreased susceptibility in 2011. In 2010, 249 STs were identified: the most common STs were ST1407, ST3150 and ST3158 at 13.3%, 11.3% and 9.0% respectively. In 2011, 238 STs were identified: the most common STs were ST1407, ST3307 and ST3550 at 15.3%, 9.3% and 5.9% respectively.

Conclusions Detecting changing antibiotic susceptibilities of N. gonorrhoeae isolates in Canada has resulted in the modification of treatment guidelines. Canada’s most prevalent NG-MAST type, ST1407 is internationally reported and is of particular interest as it is responsible for cefixime and ceftriaxone treatment failures.

FACTORS ASSOCIATED WITH VARIATIONS IN CULTURE CONFIRMATION FOR NEISSERIA GONORRHOEA: A STUDY OF PATIENTS ATTENDING FIVE GENITOURINARY MEDICINE CLINICS IN ENGLAND

H Mohammed,1 C Obi,1 C Bignell,1 G Dean,1 P Hay,1 A Robinson,1 J D C Ross,1 S Chisholm,1 C Isom,1 G Hughes,1 Public Health UK, London, UK;2 Nottingham City Hospital, Nottingham, UK;3 Royal Sussex Hospital, Brighton, UK;4 St. George’s Hospital, London, UK;5 University College Hospital, London, UK;6 Whittall Street Clinic, Birmingham, UK

Background Screening for gonorrhoea at genitourinary medicine (GUM) clinics in England is routinely performed using Nucleic Acid Amplification Tests (NAATs), but confirmation of NAAT-positive specimens by culture is required to monitor trends in antimicrobial resistance for Neissera gonorrhoea. We determined the proportion of patients whose gonorrhoea diagnoses were confirmed by culture and investigated whether they differed from those that were only screened by NAATs.

Methods All NAAT-positive attendees reported to the GUM Clinic Activity Dataset (GUMCAD, a mandatory STI surveillance system among GUM clinics in England) from 5 clinics included in the Gonococcal Resistance to Antimicrobial Surveillance Programme (GRASP) study between July–September 2011 were included in this analysis. Data from both datasets were linked by patient episode; all NAAT-positive attendees that were matched to a record in GRASP were considered culture-confirmed. Patient characteristics that were significant on Pearson’s chi-square were included in an age- and clinic-adjusted logistic regression model to determine adjusted odds ratios (aORs) for being culture-confirmed.

Results Among all 844 NAAT-positive attendees, 54% were culture-confirmed. Most attendees were between the ages of 15–34 years (70%), white (55%), and 52% of those who gave information on sexual orientation were men who had sex with men (MSM); 72% of symptomatic attendees were culture-confirmed (p < 0.001). Females and MSM were less likely than heterosexual males to be culture-confirmed (aOR(95% CI): 0.51(0.31–0.85), p = 0.010; and
0.49(0.30–0.80), p = 0.004, respectively], while those with a concurrent STI [1.69(1.15–2.49), p = 0.007], and those presenting with multiple infection sites [2.54(1.62–4.00), p < 0.001] were more likely to be culture-confirmed.

Conclusion Not all NAAT-positive attendees were culture-confirmed, but this may be because culture was either unsuccessful or not routinely performed among asymptomatic attendees. All NAAT-positive patients should be cultured before treatment, as routine culture confirmation is essential to ensure representative monitoring of trends in antimicrobial resistance to inform decisions regarding treatment guidelines for gonorrhoea.

Methods The study included all men and women in Stockholm having at least one positive gonorrhoea NAAT test with follow-up cultures taken during the period January 1, 2011–June 30, 2012. The total number of eligible cases during this period was 938. Data on sex, age, mode of transmission, symptoms, Chlamydia trachomatis co-infection and NAAT lab method were collected. Outcome was defined as positive NAAT but negative follow-up culture. Descriptive statistics and cross-tabulations with chi-squared tests were performed.

Results In total, 19% of NAAT positive cases had no positive cultures (N = 174). Diagnostic certainty was greater among men than women. Ten-percent of men and 37% of women with positive NAAT had negative cultures. Three laboratory NAAT methods were used with differences in subsequent negative culture proportions found among these methods.

Conclusion Women have an increased risk for incorrect diagnosis and/or treatment of gonorrhoea. Improved gonorrhoea testing practices are necessary to avoid systematic misdiagnoses and inappropriate treatments.

Background Gonorrhoea is the most prevalent bacterial sexually transmitted infection globally. It is of grave concern that Neisseria gonorrhoeae threatens gonorrhoea control programmes worldwide. Data on gonococcal antimicrobial susceptibility in the United States come from the Gonococcal Isolate Surveillance Project, which monitors susceptibility in male urethral isolates. Little is known about the susceptibility of isolates obtained from extra-genital sites. We sought to describe and compare antimicrobial susceptibility patterns of pharyngeal, rectal, and urethral gonococcal isolates obtained from men who have sex with men (MSM) at selected sentinel surveillance sites.

Methods We assessed the antimicrobial susceptibility of pharyngeal, rectal, and urethral gonococcal isolates collected from MSM at five sexually transmitted disease clinics throughout the United States. Minimum inhibitory concentrations (MICs) were determined by agar dilution at two regional laboratories, and elevated MICs were confirmed at the Centers for Disease Control and Prevention.

Results During December 2011-August 2012, a total of 85 pharyngeal, 99 rectal, and 315 urethral isolates from MSM were submitted. The proportion of isolates with an elevated ceftriaxone MIC was 0.79%, while those with an elevated cefixime MIC was 5.9% of pharyngeal, 7.1% of rectal, and 8.3% of urethral isolates had an elevated azithromycin MIC (p = 0.86); 1.2% of pharyngeal, 2.0% of rectal, and 4.1% of urethral isolates had an elevated ceftriaxone MIC (p = 0.47); and 2.4% of pharyngeal, 1.0% of rectal, and 1.6% of urethral isolates had an elevated azithromycin MIC (p = 0.91).

Conclusion Among MSM, the proportion of urethral isolates with an elevated ceftriaxone or azithromycin MIC was similar to that of pharyngeal and rectal isolates. These findings suggest that, at the population level, gonococcal antimicrobial susceptibility surveillance based on urethral isolates from MSM adequately represents antimicrobial susceptibility of N. gonorrhoeae circulating among MSM.
