ABSTRACT

Objective Sexual partners of injecting drug users (IDUs) are at high risk of HIV infection, yet data for such populations are scarce worldwide, particularly in the Middle East and North African region. This study measured and compared the prevalence of HIV, hepatitis C (HCV), hepatitis B (HBV) and related behavioural factors in male IDUs (MIDUs), their main female sexual partners who were also injecting drug users (FIDUPs) and their main non-injecting female partners (FNIDUPs).

Method Using convenience sampling, MIDUs were recruited at drop-in health centres in three cities (Tehran, Mashhad and Shiraz), who in turn recruited their main female partners. Behavioural data were collected using a standard questionnaire, and blood samples were drawn for HIV and HCV antibody testing and HBV surface antigen.

Results HIV prevalence was 9.4% (95% CI 2.96% to 26.2%) among MIDUs (n=226), 7.7% (95% CI 1.9% to 26.3%) among FIDUPs (n=42) and 2.8% (95% CI 0.65% to 11.3%) among FNIDUPs (n=184). HCV prevalence was 38.6% (95% CI 20.3% to 60.7%) among MIDUs, 36.6% (95% CI 13.6% to 67.9%) among FIDUPs and 8.4% (95% CI 5.67% to 12.4%) among FNIDUPs. HBV surface antigen prevalence was 3.6% (95% CI 1.5% to 8.3%), 7.3% (95% CI 1.9% to 24.8%) and 1.1% (95% CI 0.3% to 4.7%), respectively. Among MIDUs, 19.5% (95% CI 3.4% to 62.2%) had a history of sexual contact with other men. Mean age at first sexual contact in MIDUs was 19.2 years (95% CI 18.6 to 25.2) and in FIDUPs and FNIDUPs 16.4 years (95% CI 14.1 to 22.1) and 18.2 years (95% CI 15.7 to 23.1), respectively. FIDUPs and FNIDUPs had a higher mean number of sexual partners (other than their main partner) in the previous month than MIDUs (5.5 (95% CI 0 to 14.1) and 2.5 (95% CI 1.1 to 4) vs 1.3 (95% CI 0.37 to 2.2), respectively). FIDUPs tended to use drugs before or during sex with their main and casual partners more often than MIDUs (with main partner: 69% (95% CI 41.5% to 87.5%) vs 54.4% (95% CI 27% to 79.4%), respectively, and with casual partners: 47.6% (95% CI 13.1% to 84.6%) vs 34.1% (95% CI 10% to 70.6%), respectively); however, the differences were not statistically significant.

Conclusions Female partners of MIDUs in Iran and elsewhere are an under studied group. The high rate of HIV, HCV and HBV infection among females who are partners of MIDUs points to the necessity of appropriate injection and sexual risk reduction interventions among this group, to prevent acquisition of HIV, HCV and HBV and their onward transmission to other male partners.

BACKGROUND

Injecting drug users (IDUs) constitute a considerable number of people living with HIV/AIDS worldwide.¹ Due to the common parenteral mode of transmission, IDUs are also at risk of acquiring hepatitis B virus (HBV) and hepatitis C virus (HCV) infections. The sexual partners of IDUs are, in turn, at risk of HIV infection through sexual modes of transmission, and can pass the infection on to other sexual partners, or to their offspring through mother to child transmission.² In several Asian countries, the majority of females diagnosed with HIV were either partners of men who injected drugs or were sex workers.³

There are an estimated 200 000–300 000 IDUs in Iran, the majority of whom are men.⁴ Of all notified HIV cases in Iran, 8.7% are among women, most of whom were infected by their sexual partners with whom they may or may not have shared injected drugs.⁵ However, to our best knowledge, direct measures of HIV prevalence and related factors among the partners of IDUs are rare globally, and particularly in the Middle East and North Africa (MENA) region. Establishing the prevalence of HIV and related risk behaviours among IDUs, as well as their sexual partners, is critical for planning of effective prevention and intervention programmes. As the first study of its kind in Iran, this article presents findings from a survey measuring HIV, HBV and HCV prevalence and associated risk behaviours among male IDUs (MIDUs), their main female partners who inject drugs (FIDUPs) and their main non-injecting female partners (FNIDUPs).

METHODS

MIDUs were recruited consecutively using convenience sampling from four drop-in centres (DIC) serving IDUs in three large cities in Iran in 2010 (one in Tehran, one in Mashhad and two in Shiraz) and asked to participate in a bio-behavioural survey which included bringing in their main female sexual partners. DIC are supported by the Iranian government, and serve subgroups with high risk behaviours who inject drugs and who have high risk sexual behaviours. DIC provide services and support, such as methadone therapy and counselling.

Eligible MIDUs were ≥18 years old, had a history of at least one drug injection in the previous year and had at least one female partner within the past 6 months. Eligible MIDUs who had a sexual partner in the past 6 months were asked if their

partner had also consented to participate, and a time was set for them to come together with their main female partner for interview. Of the MIDUs, almost 80% attended with their partner to participate in the study. Based on the lifetime history of drug injection, partners were categorised as FIDUPs or FNIDUPs. After obtaining verbal consent, participants were interviewed by a trained professional using a standard survey questionnaire covering demographics, drug use and injection practices, and sexual risk behaviours. The partners were interviewed separately by a same gender interviewer. Dried blood spots were collected on S&S 903 filter paper and a whole blood test was carried out on each participant after obtaining separate consent for serological testing for HIV, HCV antibodies and HBV surface antigen. All testing used commercial assays for HIV (ELISA-Gene screen, BIO-RAD and confirmed with western blot-MP Diagnostic), HCV (ELISA-Dia Pro and confirmed with western blot-RIBA) and HBV (ELISA-Dia Pro and confirmed with ELISA-Gene

screen, BIO-RAD).⁶ Participants were given an incentive of US \$4 to compensate them for their participation. Results for all participants were disclosed at the DIC, with referral to care and treatment as appropriate. The study was approved by the ethics committee at Kerman University of Medical Sciences.

An a priori sample size of 230 MIDUs was calculated based on the detection of a minimum of 5% prevalence of HIV infection in their partners within a $\pm 3\%$ margin of error, with 95% CI. The data were weighted and analysed using survey analysis commands in Stata V.10 to take into account clustering at the level of the sites.

RESULTS

We recruited 226 MIDUs (mean age 37.0 years; 95% CI 34 to 40.2) and 226 main female partners (mean age 34.1 years; 95% CI 32.5 to 35.4) (table 1). Most MIDUs and FNIDUPs were married (61.0%; 95% CI 48.7% to 71.4%) and 66.7% (95%

*Male injecting drug users.

†A: MIDUs versus main heterosexual partners; A: MIDUs versus FNIDUPs. B: MIDUs versus FIDUPs.

HBV, hepatitis B virus; HCV, hepatitis C virus; MIDUs, male injecting drug users; FIDUPs, main female partners of male injecting drug users; FNIDUPs, non-injecting female partners of male injecting drug users.

CI 47.8% to 81.4%), respectively, while 26.2% (95% CI 15.7% to 40.3%) of FIDUPs were married and 40.5% (95% CI 21.2% to 63.2%) were in temporary marriages (*sigheh*). The majority of participants in all groups were educated to no higher than secondary school level.

Of the FNIDUs, 47.8% had used drugs and 18.6% (95% CI 12.6% to 26.5%) had a prior history of drug injection use. MIDUs, FIDUPs and FNIDUPs who used drugs also reported using crystal, heroin and opium. MIDUs reported starting drug use at a younger age than their partners, with a mean age at first use of 18.5 years (95% CI 17.5 to 19.6) and 21.3 years (95% CI 17.9 to 24.8), respectively. MIDUs reported starting to inject drugs at an age similar to FIDUPs (27.9 years; 95% CI 24.8 to 31.2) vs 27.4 years (95% CI 24.7 to 30), respectively). Sharing needles was more common among FIDUPs than MIDUs, reported by 55.0% (95% CI 39.5% to 70.6%) compared with 39.1% (95% CI 30% to 50%), respectively.

Table 1 shows the multiple sexual risk behaviours reported by the three groups. Women were younger at first sexual contact than their MIDU partners, at 16.4 years (95% CI 14.1 to 22.1) for FIDUPs compared with 18.2 years (95% CI 15.7 to 23.1) for FNIDUPs and 19.2 years (95% CI 18.7 to 25.2) for MIDUs. Most MIDUs (72.7%; 95% CI 46.5% to 85.6%) and FIDUPs (78.6%; 95% CI 44.5% to 94.4%) reported casual partners (other than the main one they came with); FNIDUPs had a high mean number of partners in the past 6 months (5.5 (95% CI 0 to 14.1) casual partners). Reported condom use and drug use before or during sex tended to be higher with the main partner compared with casual partners. Injection and non-injection drug use before or during sex was common among MIDUs and FIDUPs (54.4% (95% CI 27% to 79.4%) and 69.0% (95% CI 41.5% to 87.5%), respectively with main partners, and 34.1% (95% CI 10% to 70.6%) and 47.6% (95% CI 13.1% to 84.6%), respectively with casual partners) and yet a substantial fraction of the FNIDUPs also used drugs with sex with their main partners (29.7%; 95% CI 18.6% to 43.8%) and with casual partners (11.4%; 95% CI 5.1% to 23.8%). Symptoms of sexually transmitted infections, such as genital ulcers and genital discharge, were also fairly common for both types of female partners. MIDUs tended to have a lower level of comprehensive knowledge of HIV/AIDS than their female partners (22.5%; 95% CI 2.81% to 74.4% vs 30.4%; 95% CI 7.4% to 70.3%, respectively) although the difference was not statistically significant.

The prevalence of HIV and HCV in MIDUs tended to be higher than in FIDUPs and FNIDUPs. HIV prevalence was 9.4% (95% CI 2.96% to 26.2%) in MIDUs compared with 7.7% (95% CI 1.9% to 26.3%) and 2.8% (95% CI 0.65% to 11.3%) in FIDUPs and FNIDUPs, respectively. HCV prevalence was 38.6% (95% CI 20.3% to 60.7%) in MIDUs compared with 36.6% (95% CI 13.6% to 67.9%) and 8.4% (95% CI 5.67% to 12.4%) in FIDUPs and FNIDUPs, respectively. The prevalence of HBV was lower in MIDUs than in FIDUPs, but higher than in female FNIDUPs (3.6% (95% CI 1.5% to 8.3%) vs 7.3% (95% CI 1.9% to 24.8%) and 1.1% (95% CI 0.26% to 4.7%), respectively). Fewer than one in five in any group had been tested for HIV in the past 12 months and received their results (13.3% (95% CI 6.2% to 26.2%) of MIDUs, 16.7% (95% CI 5.3% to 41.5%) of FIDUPs and 14.1% (95% CI 5.9% to 30.4%) of FNIDUPs). Among the participants, two couples were HIV concordant positive—that is, both the man and woman were HIV positive. One of these couples involved an FNIDUP and the other involved an FIDUP.

DISCUSSION

To our knowledge, this study is one of only a few in the MENA region that has measured the level of HIV infection among female sexual partners of MIDUs—a key group at risk of HIV infection that has been largely neglected or has been beyond the reach of researchers in this region. Through their MIDU partners, we obtained rare samples of female partners of IDUs. Our results showed that HIV prevalence was higher among FIDUPs (7.7%) compared with FNIDUPs (2.8%), mainly because of the dual risk of unsafe injection and unprotected sex. Moreover, HCV affected more than one-third of MIDUs and FIDUPs and 8.4% of FNIDUPs. These results are of great concern in Iran, as the per capita prevalence of injecting drug use is quite high.⁴ In the province of Kerman (not the study setting) for example, it was estimated that the prevalence of injecting drug use among males aged 18–45 years was 1.2%.⁷ Substantial levels of HIV, HCV and HBV infection among IDUs have already been documented in Iran, with a prevalence of approximately 10.7%, 34.5% and 50.7%, respectively.⁸

The relevance of partners of IDUs to HIV dynamics was illustrated in a recent modelling study that estimated HIV incidence by mode of exposure. According to the study, about 1000 new HIV infections per year occur among the partners of IDUs in Iran—the second highest level of HIV incidence after IDUs.⁹

Our results provide a rare insight into the sexual risks of women within the sexual networks of MIDUs in Iran. In our survey, many women and men reported having casual sexual partners in addition to their main partner. We hypothesise that a number of participants may have been sex workers during the past month. Due to the situation in Iran, where potentially severe penalties exist for sex workers, we chose not to ask this question directly. But if this is true, the overlap of these different key populations can create opportunities for bridging HIV infection to other subpopulations, such as female sex workers. Temporary marriage (*sigheh*, which is a type of marriage with a flexible but predetermined duration), may also facilitate HIV transmission through the formation of multiple and potentially concurrent partnerships.

Taking into account the stigma that exists around high risk behaviours in Iran, some of our self-reported measures may have been affected by underreporting bias. Moreover, this was a facility based study and accordingly prone to selection bias and may not be generalisable. Due to the nature of the affected populations, our method of recruitment was the most feasible option to conduct this study.

Female partners of IDUs have received inadequate attention with respect to care and prevention programmes in Iran, and likely elsewhere in the MENA region. This is of concern not only because of the risk of HIV acquisition, but also because of the risk of mother to child transmission. Our study calls for further research in the region to understand the vulnerability of spouses and other partners of MIDUs and to explore avenues by which this vulnerability can be addressed. HIV surveillance programmes for female partners of IDUs are needed. Given that the levels of HIV infection in the general population at large are still very low, general population based interventions may not be cost effective and may be confronted by multiple logistical barriers.¹⁰ However, people who use illicit drugs could be targeted for specific interventions.¹¹

Targeted interventions may have the potential for more success, but access to women at risk may be difficult. Novel approaches to HIV prevention among these women, which are appropriate for the MENA context, are urgently needed, with

the increasing evidence for emerging and established HIV epidemics in MENA.¹² Our success in reaching and recruiting these women through their MIDU partners offers a promising starting point, and this approach of recruitment of female partners could be applied to the provision of appropriate interventions.

Key messages

- ▶ High levels of HIV and hepatitis C virus infection are found among injecting drug users and their main female sexual partners.
- ▶ Injecting and sexual risky behaviours are common among injecting drug users and their main female sexual partners.
- ▶ Female sexual partners of injecting drug users are a key vulnerable population at risk of HIV infection and may play a role in bridging HIV infection to other population groups.
