PENICILLIN TREATMENT OF CARDIOVASCULAR SYPHILIS*†

BY

HERMAN BEERMAN

University of Pennsylvania, Departments of Dermatology of the School of Medicine (Professor D. M. Pillsbury) and of the Graduate School of Medicine (Chairman, H. Beerman), and the Institute for the Study of Venereal Disease (Director, J. H. Stokes)

Any evaluation of a new mode of therapy for cardiovascular syphilis is bound to yield inconclusive results because of the many unsolved problems in diagnosis, and because of the lack of suitable controls. It is however the author’s conviction that in penicillin practitioners have a safe, effective means of supplementing the medical treatment of cardiovascular syphilis.

Evaluation of Treatment

Among the still unsolved problems in the evaluation of penicillin therapy are:

1. uncertain criteria of diagnosis, clinical and post-mortem, of uncomplicated syphilitic aortitis;
2. influence of race and sex;
3. prophylactic effect;
4. amount of treatment adequate in early syphilis to prevent the development of cardiovascular complications.

Furthermore, insufficient time has elapsed to determine the efficiency of penicillin in the management of cardiovascular syphilis. Evaluation of the effect of penicillin therapy on prognosis is also difficult because we do not know whether or not cardiovascular syphilis is changing with the passage of time, so that we are now seeing a different type of this phase of syphilis. The simultaneous occurrence in patients of cardiovascular and other forms of late syphilis, such as neurosyphilis, may alter the picture of therapeutic efficacy, besides increasing the potential reactivity of the patient to a particular treatment system or drug. Other variable factors involved are:

- the presence of diabetes mellitus;
- hypertension;
- degree of arteriosclerosis;
- renal function.

It is not sufficient merely to use past records to obtain a control series against which to evaluate therapy in cardiovascular syphilis. One cannot be certain whether patients in the previously treated group are similar to those now being subjected to the new method of treatment (Densen and others, 1952).

Barnett and Small (1950), moreover, on the basis of a series of 334 cases of cardiovascular syphilis with aortic regurgitation, aneurysm, or both, attest to the statistical difficulties in the evaluation of the effect of antisyphilitic therapy in cardiovascular syphilis. They show that symptomatic and asymptomatic cases must be separated for study. In the former, cases observed for less than a year must be eliminated in order to obtain little- and much-treated groups of comparable initial severity. In the latter, no such elimination can be made, but the results must be expressed in relation to the total years of patient observation, rather than to the number of individual patients involved. Antisyphilitic therapy probably improves prognosis to some extent at any stage of cardiovascular syphilis, but it is definitely more effective when given before the onset of symptoms, and it probably becomes progressively less useful as the disease progresses. Flaum and Thomas (1951) believe that the factors influencing prognosis of cardiovascular syphilis include:

1. presence or absence of symptoms of diminishing cardiac reserve;
2. size of heart;
3. age of patient (arteriosclerosis);
4. type of work performed;
5. amount of previous antisyphilitic therapy and when it was given in relation to the discovery of the cardiac involvement.

Involved also in the evaluation of cardiovascular syphilis therapy is the relative place of medical care, other than so-called specific therapy. Although little mention is made here of the so-called medical treatment of cardiovascular syphilis, this does not indicate any lack of regard for its importance.

* Address given to the Medical Society for the Study of Venereal Diseases on July 26, 1952.
† Reprinted and slightly abridged from the Progress of Medical Science Section of the American Journal of the Medical Sciences, (1952), 224, 446, with the permission of the Editors and Publishers.
The review of cardiovascular syphilis by Moore (1949) summarizes many of the problems involved in determining the effect of antisyphilitic therapy in this aspect of syphilis. In view of the uncertainty of diagnosis of uncomplicated syphilitic aortitis, information concerning the effect of antisyphilitic treatment must be sought from patients in whom the clinical diagnosis is as nearly as possible verified by the presence of aortic regurgitation, saccular aneurysm, or both. In this connexion, Moore believes that only two methods of study seem applicable; the histopathology of aortic syphilis as affected by treatment and the clinical study of treatment effect.

The study of the effects of therapy on the histopathology of the aorta, however, has yielded contradictory results. While Hood and Mohr (1937) found no histologic differences in the aortas of untreated and adequately treated patients, Howe (1943) and Webster and Reader (1948, 1949) found what appear to be definite differences.

Moore points out certain difficulties in the clinical study of the effect of treatment in terms of symptomatic relief and prolongation of life span. The first clinical intimation of the presence of cardiovascular syphilis may be sudden death, or an attack of congestive heart failure, which is fatal in a few days or weeks. In such cases, there is no way of estimating the value of specific treatment, since there is no time to give it. Because the Johns Hopkins material contains nearly one-third of the cases of cardiovascular syphilis in this category, Moore and his group eliminate from statistical consideration of treatment effect all patients who died within one year of the onset of symptoms. Furthermore, since in a given patient the course of the disease is wholly unpredictable with or without therapy, conclusions may be drawn only from large numbers of individuals and in terms of averages. Aortic regurgitation, saccular aneurysm, or a combination of the two, are usually fatal in the long run, unless the patient dies of an unrelated process.

The uncontrollable factors of the economic situation and physical work are related to mechanical circulatory death. A sedentary occupation is essential to prolong life to the maximum in a patient with aortic aneurysm or regurgitation. The factor of work stress is, according to Moore, as important in prolonging life as antisyphilitic treatment, and account must be taken of it in a statistical analysis of results. Because of the more strenuous occupations of males, sex plays an important role in prognosis. The race of the patient is also important; for example, syphilitic heart disease is not only more frequent in the Negro than in the white, but it is probably also more rapidly progressive. The duration of infection and the age of the patient are also involved. The probably prolonged symptomless course of aortic insufficiency and aneurysm is a significant item. An estimate of the effect of antisyphilitic treatment can be had only by comparison of various groups of patients receiving various types or amounts of specific therapy with a group receiving none at all. The purely medical management of the several groups must be as far as possible identical. The physician must resist the temptation to try another form of antisyphilitic therapy if one fails to bring about symptomatic relief, or if symptoms recur. Finally, for complete statistical accuracy, Moore suggests that the results of treatment should be reported only for patients followed until death; if possible, with verification of the diagnosis by necropsy.

Results of Metal Chemotherapy in Cardiovascular Syphilis

Moore's summary of this problem is so satisfactory that it is quoted below at length:

These complexities are cited in extenuation of the fact that now, nearly 40 years after the first introduction of salvarsan by Ehrlich and the initiation of effective metal chemotherapy, there are available in the world literature only three comparable, and reasonably statistically reliable studies of the effect of antisyphilitic therapy in cardiovascular syphilis. These are by Grant (1933), Padget and Moore (1941), and Stratton (1935).

Depending on the biostatistical method employed, even Grant's data are not strictly comparable with the other two series. Based on 171 cases of aortic regurgitation followed for 10 years or until death, Grant indicates that the mortality rate is higher, and especially so from cardiovascular syphilis, in patients untreated or inadequately treated (with potassium iodide only) than in those given something approaching reasonable arsenic and heavy metal therapy; and that the proportion of patients still living 'uneventful and unchanged' after 10 years is higher in the treated group. If, however, one re-analyses Grant's material on the basis of average duration of life after onset of symptoms, limiting the analysis to patients already dead, there is no difference in the two groups (89 months in 29 treated patients, 87 months in 89 untreated patients). The average duration of life in Grant's untreated group is greater than in treated patients in the two American series. There is, however, a significant difference in the clinical material. Grant's patients were all white males, British Army pensioners, who were able to lead an essentially sedentary life. In the two American series, the patients are predominantly Negro labourers, in whom the unfavourable influence of hard physical work is repeatedly evident.

The data of Padget and Moore and of Stratton, combined and refugured to show the average duration of life in sixty patients with saccular aneurysm (32
untreated, 28 treated) and 91 patients with aortic regurgitation (51 untreated, forty treated), all of whom lived at least one year after the onset of symptoms or recognition of the lesion but all of whom were dead at the time of study, indicate that life span may be approximately doubled by the factor of treatment.

The actual figures are:
- aneurysm untreated, 41 months, treated 74 months; aortic regurgitation untreated, 45 months, treated, 75 months.

The data of Reader and his associates (1947) cannot be compared for lack of pertinent information, but also strongly suggest that antisyphilitic treatment is effective in prolonging life.

All these results were obtained with prolonged cautious treatment with arsenic, bismuth, and mercury, as outlined in Chapter 18 of my monograph, "The Modern Treatment of Syphilis" (Moore, 1941).

**Therapeutic Shock and Paradox**

In the conventional therapy of cardiovascular syphilis, two concepts, therapeutic shock and therapeutic paradox, played an important role. These problems are fully discussed in "Modern Clinical Syphilology" (Stokes, Beerman, and Ingraham, 1944), and in papers by Stokes, Wolfert, Edeiken, Falk, and Ford (1951), Butterfly and Fishman (1952), and Mohr and Hahn (1952).

**Therapeutic Shock.**—The former, commonly spoken of as the Jarisch-Herxheimer or Herxheimer reaction, is a flare-up of the disease upon the institution of treatment. Originally described by Jarisch for the secondary eruption under treatment with mercurial inunction, it has been identified in every observable phase of syphilis, early and late. In the use of the arsenicals its intensity up to the point of destructive violence probably depends in part upon the initial intensity and impact of the treatment, though the "allergic" status of the individual also participates in this reaction. Dosage, and the activity of the treatment agent used, both play a role in its production. Its mechanism is still unknown, but the earlier attributing of the flare to lysis of *Treponema pallidum* at lesion sites is certainly untenable, since the reaction appears after the use of relatively nontoxic drugs, for example, mercury and tryparsamide, and can be seen in lesions of late syphilis in which treponemata are few and far between. It is more probable that at least a part of the reaction is in the cellular tissues and of the nature of an immunity response, or even an allergic reaction. Therapeutic shock induced by metal therapy had to be controlled. This was accomplished by two devices: initial low dosage, and the preliminary use, before the more shock-producing arsenicals were administered, of more or less prolonged "preparation" with the slower-acting heavy metals, although bismuth itself may produce therapeutic shock, and neoarsphenamine can be given without serious clinical shock if the dosage is low enough.

Clinically the Jarisch-Herxheimer reaction may be manifested by increased body temperature as well as by a flare-up of obvious or subclinical syphilitic lesions immediately after treatment with anti-syphilitic agents. In the heart this could result in serious embarrassment. Therapeutic shock, then, has been accepted as a danger in the treatment of cardiovascular syphilis during the middle and later years of the arsenical era, and has discouraged the full use of our therapeutic resources against syphilis in treating the disease in the heart and great vessels. On the other hand, the vasculotoxicity of the arsenicals as such should not be confused with the Jarisch-Herxheimer reaction.

**Therapeutic Paradox.**—Wile (1922) first described this as the conception that the patient might be injured even fatally by the rapidly induced healing of a syphilitic lesion in a vital structure. This was originally observed in the liver. Syphilitic hepatitis improved rapidly under the arsenamines, and then with equal rapidity the patient went downhill to uncontrollable ascites, with other evidence of hepatic injury, portal obstruction, and death. Later the concept was broadened to include other late manifestations of syphilis, and supposed fibrous contractile scarring as a phase of the healing process, with shrinkage and distortion of the involved structure, rather than lack of time for functional adjustment, was emphasized as the evil consequence. The mechanism of the therapeutic paradox is still unknown. It may be prevented much in the same way as therapeutic shock. Even substitution of a less toxic arsenical (arsenoxide) may, because of lessened vasculotoxicity, yield fewer therapeutic paradoxes than the arsenamines.

**Sources of Pertinent Information**

For the student of the treatment of cardiovascular syphilis, a number of good sources are available. Among these are: Stokes, Beerman, and Ingraham (1944), Fleming (1948), Kampmeier (1946), Cole and others (1936), Hinrichsen (1943), Woodruff (1948), de la Chapelle (1947), Nicol (1950), Cormia (1935), Eisenberg (1948), Chapman and Morgan (1947), Prebble (1951), Webster (1947), Barnett and Small (1950).

**Penicillin in Cardiovascular Syphilis**

Since penicillin should theoretically behave like the other fast-acting spirillicides, the arsphenamines, it could produce not merely a febrile reaction, but an overall exacerbation of the syphilitic process, transient and serious in proportion to the vital location of the lesion and the size of the initial dose. Early in the penicillin era, workers attempted to control an anticipated shock effect by reduction in dosage, but the observation of Olansky (1947) seemed to indicate that reductions in dosage to as low as 1,000 units were without effect in preventing Herxheimer reactions, though their intensity might conceivably be reduced. Tucker and Farmer (1947) showed that a febrile Herxheimer reaction fails to appear only below such small doses as 1 to 10 units.
PENICILLIN IN CARDIOVASCULAR SYphilis

kg. body weight. One-tenth of the dose that will render a syphilitic lesion darkfield negative is capable of causing a Jarisch-Herxheimer reaction. Purified crystalline penicillin G appears to yield fewer severe local flares and immediate serious reactions as compared with the arsphenamines. Certain groups (notably at the University of Pennsylvania) have made a complete study of the effects on cardiovascular syphilis, but other investigators have been extremely conservative in their exhibition of a rapid-acting drug like penicillin, e.g., Wile (1945), Peralta and Castaneda (1949), Tung (1948), Eisenberg (1948), Blomquist (1948), and Willcox (1951). For example, Wile advised against the use of too intensive methods. He felt that after the disease had reached a clinical horizon, treatment reactions were more apt to occur. This relates to either the arsenicals or penicillin, both of which are fast-acting drugs. This point of view seemed somewhat justified at first because in a disease process, such as cardiovascular syphilis, where sudden death, with or without treatment, is frequent, treatment with even small doses of penicillin seemed to be unsafe. Early reports, although admittedly equivocal, featured reactions, even fatal, in patients with cardiovascular syphilis under penicillin therapy. (Dolkart and Schwemlein, 1945; Callaway and others, 1946; Moore, 1949; Scott and others, 1949; Porter, 1948.) Subsequent experience indicates that penicillin is not only well tolerated, but may actually induce relief of symptoms and prolongation of life. Data obtained from the literature have been tabulated in chronological order in the Table (pp. 22–27).

Jarisch-Herxheimer Reaction and Therapeutic Paradox.—The literature on penicillin therapy of cardiovascular syphilis shows how groundless were the fears that it would produce an excessive number of therapeutic shocks and paradoxa. Moore, Farmer, and Hoekenga (1948) stated that the febrile response of the Herxheimer reaction was rarely observed in cardiovascular syphilis, and then only in patients with an associated neurosyphilis with active cerebrospinal fluid findings. They observed no clinical suggestion of increased cardiovascular damage, nor could any evidence of this be detected by serial electrocardiograms, leucocyte counts, and sedimentation rate estimations. The Johns Hopkins group believed that

the risk of a serious Herxheimer reaction in cardiovascular syphilis has been grossly exaggerated.

Wheeler and Curtis (1951) of the University of Michigan analysed the reported deaths and reactions as follows:

Of the eight possible reactions, there are reported three fatalities. The patient reported on by Porter had received four months of bismuth and iodide therapy before penicillin was administered. Two days after 9-6 million units of penicillin had been given the patient died of rupture of a huge aneurysm. It was evident before treatment that rupture of this aneurysm was imminent and it is impossible to say whether treatment had anything to do with the course of events. In the case presented by Moore the cause of death was likely cardiac failure which developed on the fourth day of treatment. The aorta was filled with plaques of syphilitic aortitis each of which contained fresh hemorrhage. Evaluation in this instance is complicated by the patient’s being treated with malaria as well as penicillin. Scott and Maxwell’s patient suffered from purulent meningitis of unknown cause. Response to penicillin seemed satisfactory, but the patient died suddenly during convalescence of rupture of a previously unsuspected aneurysm. The possibility of bacterial involvement of the vessel was not discussed.

Of the eight possible reactions there are five reports indicating temporary interference with cardiac function. One of Porter’s two patients had received 2 weeks and the other had received 2 months of potassium iodide and bismuth therapy before penicillin was given. Each had aortic insufficiency and one also had an aortic aneurysm. Both were in congestive failure before penicillin was given. As good ‘compensation as possible’ was obtained by use of digitalis, diuretics, and bed rest. Each developed increasing evidence of congestive failure 2 weeks after penicillin was begun. Each responded satisfactorily to diuretics and greater curtailment of activity. The observation that congestive failure associated with syphilitic aortic insufficiency may be refractory to treatment and that it tends to recur casts some doubt on the conclusion that these patients present evidence of the therapeutic paradox.

Dolkart and Schwemlein’s first patient was seen in 1941, at which time diagnoses of latent syphilis and rheumatic heart disease with mitral stenosis and aortic stenosis were made. From 1908 to 1935 the patient had received an unknown amount of arsenic and bismuth. During 1942, an aortic diastolic murmur became evident. On two occasions in 1943 the patient was hospitalized because of chest pain and dyspnea. In 1944, he was again hospitalized and treated for congestive failure. In the summer of 1944, anginal pain on strenuous effort was noted. During 1942 and 1943, fifty doses of bismuth were given. The patient was rehospitalized in September, 1944, for penicillin therapy. Ten thousand units of penicillin given on September 24 produced no reaction. After 20,000 units on September 25, the patient noted four episodes of anginal pain. Twenty thousand units were given again on September 25 and 20,000 units 3 times on September 26. Seven episodes of anginal pain were noted on September 26 and ventricular extrasystoles appeared on physical and electrocardiographic examination. The penicillin was stopped. The extrasystoles disappeared. Because of the associated rheumatic heart disease, the amount of pretreatment, the evident cardiac dysfunction before penicillin was given, it is hazardous to claim that this is an example of a Herxheimer reaction.

The second patient reported by Dolkart and Schwemlein was given penicillin for an upper respiratory infection. After 700,000 units given over a

</table>
3-day interval, precordial pain appeared. The penicillin was stopped and the pain disappeared by the following morning. This patient had aortic insufficiency and tabes dorsalis, the diagnosis being made in 1936, nine years before penicillin therapy. From 1936 to 1939, he was given intermittent treatment consisting of iodides, bismuth, and neoarsphenamine. In 1938 and 1939, several episodes of precordial pain had occurred, but the patient denied precordial pain from 1939 to 1945. He also denied knowledge of syphilis or of specific treatment for it. Besides a possibility that the history was unreliable, the reappearance of the precordial pain at the time of penicillin therapy may have represented only coincidence. It might even be that the pain was tabetic.

The report of Callaway and his associates concerns a 42-year-old carpenter who received penicillin in the treatment of neurosyphilis. At the time of treatment compensated aortic insufficiency was observed. No reaction during therapy was noted. When the patient returned to work 10 days after therapy, precordial pain appeared. The pain was progressive. About 6 weeks later the patient went into congestive failure. The murmur had taken on a harsh quality suggestive of a ruptured aortic cusp. Treatment for congestive failure restored compensation but the cardiac reserve was too low to permit the patient to return to work. Rupture of a valve was not proved by autopsy. In the event of valve rupture, it is unlikely the patient could regain compensation. It is impossible to prove whether the breakdown of cardiac reserve was a result of the penicillin therapy or whether it represented a natural progression of the disease.

A review of the present literature dealing with the use of penicillin in cardiovascular syphilis indicates that about 190 cases have been reported. About 35 of these patients carry diagnoses of uncomplicated aortitis. Since a diagnosis of uncomplicated aortitis is subject to considerable possibility of error, results pertaining to this group of patients should be accepted with reserve. The remaining 155 patients present evidence of either aneurysm, aortic insufficiency, or both, and as such permit diagnoses of cardiovascular syphilis. Of this latter group, approximately 130 patients have been given varying amounts of iodide and metal therapy before penicillin administration, and about 25 have received no pretreatment before penicillin therapy. In no instance has an unquestionable adverse reaction to penicillin therapy been recorded.

Whorton and Denham (1951), who reported the occurrence of a possible Jarisch-Herxheimer reaction after penicillin treatment in a patient with gummatous syphilitic aortitis, also commented on the rarity of the Jarisch-Herxheimer reaction in cardiovascular syphilis, in contrast with early syphilis and central nervous system syphilis.

Encouraged by the relatively lessened reaction tendency of penicillin G over the more crude product, Edeiken and others (1949), reported the results of the treatment of fifty cases of cardiovascular syphilis with penicillin therapy alone, without preparation; and of twelve patients with cardiovascular syphilis and congestive failure, in whom penicillin and methods to combat congestive failure were used simultaneously. In this group, not only were untoward effects lacking, but the distinct impression prevailed that these patients responded better than most patients with cardiovascular syphilis and decompensation who were treated, as was often the case in the pre-penicillin era, with measures aimed only toward combating congestive failure. Experience with these two groups of cases led to the belief that therapeutic shock in cardiovascular syphilis treated with penicillin is indeed uncommon; and that therapeutic paradox, if it occurs, is a rarity. Various hypotheses, including that of a toxic action of arsenicals upon already diseased tissues, rather than a wholesale sudden liberation of toxic spirochaetal disintegration products, were discussed to explain therapeutic shock. If therapeutic paradox occurs, they do not believe it is common or that it is caused by too rapid cure with disturbance of function and resultant rapid fibrosis.

Subsequently Edeiken and others (1951) reported observations on 111 penicillin-treated cardiovascular syphilitic patients (simple aortitis, 48; aortic regurgitation, 51; aortic regurgitation and aneurysm, 9; aneurysm, 3), with re-emphasis of the virtual absence of significant therapeutic shock and paradox.

Serologic Effects.—The serologic effects of penicillin therapy on cardiovascular syphilis are bound to be disappointing. The frequent association of neurosyphilis with syphilitic cardiovascular involvement (for example, 45·2 per cent. of the 111 patients mentioned above also had central nervous system syphilis) may account for much of the poor serologic effect of treatment. Edeiken and others (1951) found, disregarding the six cases without follow-up, that there were 85 cases (80·9 per cent.) positive before, and 86 cases (81·9 per cent.) positive after therapy. Twenty cases (19·1 per cent.) were negative before, and nineteen cases (18·1 per cent.) negative after treatment. Although seven of the cases with a sero-positive reaction yielded negative reactions after treatment, eight of the original twenty cases that had negative reactions before treatment were sero-positive after penicillin therapy. Thirty-six (42·3 per cent.) of the 85 patients with positive results in their tests showed a drop of two or more tubes in the quantitative test, and 37 (43·5 per cent.) showed no change in the quantitative tests. Coale and others (1950) had similarly poor serologic results, and Weir and others (1950) and Johnson and Shapiro (1951) found a post-penicillin therapy drop in serologic titre in their relatively small
series of cases. Leech (1950) found that three out of seventeen patients developed negative reactions to the Wassermann or Hinton tests after treatment.

Clinical Effects.—Assuming that all the deficiencies previously mentioned as inherent in the determination of the effect of penicillin therapy of cardiovascular syphilis are corrected, one could not make definite statements regarding the clinical effectiveness of such treatment because the period of observation is as yet rather short. Up to 1951, 1,243 days was about the longest period of observation reported (Johnson and Shapiro, 1951). However deficient the data, some of the information available on this aspect of the problem is worth mentioning.

Coale and others (1950), for example, noted no striking results, but the overall picture was good.

Flaum and Thomas (1949) stated that seven of their patients with aortic insufficiency, “claimed to be improved after treatment.” This apparent improvement could be due to a general systemic improvement following the eradication of the chronic low-grade syphilitic infection.

Leech (1950) reported that all but two of his patients were improved or unchanged. Death in three was not attributable to treatment.

Chapman and Morgan (1947) observed relief of pain in patients with aneurysm, but their treatment schedule included potassium iodide and bismuth simultaneously.

Wheeler and Curtis (1951) also reported improvement in symptoms, but there were two possible therapeutic paradoxes.

Johnson and Shapiro (1951) found significant orthodiagnostic and roentgenographic changes indicating enlargement of an aneurysm in one patient who died of tracheal obstruction 2 days after completion of treatment. Five patients died 2, 270, 350, 537, and 854 days, respectively, after treatment. Most of the patients experienced weight gain and a feeling of well-being.

Weir, Roberts, and Tallis (1950), in a preliminary comparison of the post-treatment with the pre-treatment status of their patients, indicated that, although a few patients were graded as “worse” in the post-treatment period, in no case was deterioration hastened by penicillin therapy.

Edeiken and others (1951) found that:

penicillin is admirably tolerated by the decompensated heart, with clinical improvement in a high proportion of cases. Anginal pain was relieved without recognizable shock or paradox in four out of five cases. In syphilitic aortitis ‘uncomplicated’, observed for from 3 to 58 months, one-third were improved, one-half unchanged, and only one-sixth were worse (one death of bronchopneumonia). In aortitis with regurgitation, 64 per cent. were improved, 20 per cent. unchanged, and 16 per cent. worse. In aneurysm with regurgitation the number was too small for analysis, but four or five kept under observation improved. Of three patients with large saccular aneurysms, one lapsed from observation, one died in a wiring operation, and one showed no change.

Electrocardiographic Changes.—In this phase of the subject, it is necessary to differentiate the electro-cardiographic effects induced by penicillin per se and those incidental to the changes in cardiovascular status that this therapeutic agent induces. Steiger and Edeiken (1948), in their studies on the electro-cardiographic changes before, during, and after penicillin treatment in early syphilis, found alterations in 42.5 per cent. of a second series of forty cases. In an earlier report (1947), they had found a 50 per cent. incidence among thirty cases, making an aggregate of 45.7 per cent. of seventy cases. The electrocardiographic changes, which were T-wave and in some cases RS-T sequent changes in limb or chest leads, or both, occur in all phases of early syphilis. Penicillin does not seem to be responsible for these changes. The changes are usually transient, but may be permanent.

Binder and others (1950) encountered transient T-wave inversion in three patients who developed severe reactions during penicillin treatment. These resemble changes observed in other allergic reactions. With respect to the electro-cardiographic changes produced by penicillin in the treatment of cardiovascular syphilis, there are only scattered data, the exact significance of which is not clear. Edeiken and others (1949) state that, although a large percentage (50 per cent.) of their cases showed electrocardiographic abnormalities either before, during, or after penicillin treatment, one cannot conclude that they are all directly or solely due to the syphilitic infection. Significant T-wave changes were noted during the course of treatment in eight patients. Moore (1949) observed that tracings taken during the course of treatment did not indicate that penicillin irritated the heart, and in several instances improvement was seen. Peralta and Castaneda (1949) noted that 7-8 per cent. of their patients had altered electrocardiograms. Coale and others (1950) concluded that nothing definite could be concluded by following the electrocardiograms. Johnson and Shapiro (1951) observed that:

...the electrocardiographic tracings, except for changes which go with left ventricular strain due to aortic insufficiency or changes due to coronary involvement, showed no pattern which could be considered pathognomonic of cardiovascular syphilis.
Summary Statement and Proposed Therapeutic Regimen

The problems of penicillin therapy of cardiovascular syphilis may now be summarized by asking and answering the questions posed by Edeiken, Ford, and Stokes (1951). We emphasize again the relatively subjective character of the available information:

(1) Can penicillin therapy be given safely to patients with cardiovascular syphilis?

Penicillin is relatively free from severe reaction.

(2) How common is therapeutic shock and therapeutic paradox in penicillin-treated cardiovascular syphilis?

Relatively few unequivocal reactions have been observed, and the University of Pennsylvania group observed no serious examples in 111 cases. The role of coincident neurosyphilis in producing febrile Herxheimer reactions is re-emphasized.

(3) Are there any contraindications to the use of penicillin in cardiovascular syphilis?

Patients exhibiting a variety of processes, previously contraindicating arsenical therapy, have been given penicillin treatment without serious untoward effects.

(4) Does penicillin stop the progress of cardiovascular syphilis?

There is evidence to suggest that the course of the disease is favourably influenced by penicillin, but no definite statement can be made before a long follow-up period of at least 10 years has elapsed, and before a large number of cases have been studied clinically and pathologically.

(5) What effect has treatment on the serologic test for syphilis?

The information indicates that little may be expected from treatment in the way of serological reversal. The coincidence of neurosyphilis with the cardiovascular process plays a large role in this lack of serological reversal.

(6) Should patients with suggestive, but not positive, signs of aortitis be treated with penicillin?

We agree with Edeiken, Ford, and Stokes in saying "yes" to this question. In view of the uncertainties in the diagnosis of uncomplicated syphilitic aortitis and the safe and probable effectiveness of penicillin therapy, the patient should be given the benefit of the doubt, not only because it is practically without danger, but also because it is inexpensive and not time-consuming. In the past, many patients were not treated because even a presumptive diagnosis condemned them to a prolonged, costly, and even dangerous therapeutic regimen.

To these questions may be added:

(7) Is treatment with bismuth and iodides necessary before penicillin therapy of cardiovascular syphilis?

Although, according to Willcox (1951), most British physicians are employing such preparatory treatment, it is obvious from the data presented above that this seems unnecessary at least from the reaction standpoint. Whether the eventual outcome of treatment will be better with combined therapy or penicillin alone is still unanswered.

Assuming, from the data presented, that penicillin is the safest agent yet produced for treating cardiovascular syphilis, we suggest that the treatment scheme of the University of Pennsylvania group (Edeiken and others, 1951) be employed until a more convenient or effective regimen is evolved.

The advocated treatment includes hospitalization and a 2-hour schedule of crystalline penicillin G (4,800,000 to 9,600,000 units in 40,000 to 80,000 unit individual doses), but procaine penicillin may be given to hospitalized patients on a 600,000 unit single, or a 300,000 unit two-injection daily schedule to an equivalent total dosage. The ambulatory use of this salt is under investigation. By present standards, repetition of courses in excess of two of 9,000,000 units seems unnecessary. . . . The concomitant or subsequent use of heavy metals was not studied in this series, but seems on general experimental grounds to be unnecessary.
