SUMMARY We report the transmission of genital herpes simplex virus (HSV) infection from an asymptomatic woman shedding virus from the cervix to two male sexual partners and further transmission from these two men while their infection was in the prodromal phase. The value of the restriction enzyme analysis of viral deoxyribonucleic acid (DNA) is presented. Guidelines regarding the management of patients who are found to be asymptomatic shedders of HSV are discussed.

Introduction

Epidemiological studies of the transmission of genital herpes simplex virus (HSV) infection have been made more accurate by characterisation of viral deoxyribonucleic acid (DNA) by restriction endonuclease analysis.¹⁻³ We report the use of this method to study the transmission of genital HSV infection by an asymptomatic woman shedding virus from the cervix and to investigate viral isolates from subsequent recurrences of HSV infection.

Case report

A man aged 26 (case A) presented to the Praed Street Clinic complaining of penile ulceration of 24 hours' duration. He had had itching and redness of his penis and the systemic symptoms of headache, fever, and myalgia for five days. He had no history of any sexually transmitted disease (STD) or of oral HSV infection. A clinical diagnosis of genital herpes was made, which was confirmed by isolating the virus. The absence of complement fixing antibody to HSV showed that this was a primary episode. At the first visit, he reported that his elder brother (case B) had similar symptoms and also gave a sexual history (table) that suggested a common source of their problems.

We traced the female consort (case C), aged 33, who agreed to attend the clinic on the following day. She was symptomless and had no history of STD or of

HSV infection. On examination of her cervix, erythema and a mucopurulent discharge were visible, and colposcopic examination showed ulceration on the ectocervix. Routine tests for gonorrhoea, candidiasis, trichomoniasis, and chlamydial infection gave negative results, but HSV was isolated from the cervix. Complement fixing antibody to HSV was detected in her serum, with no significant change in titre three weeks later, which suggested that this was a recurrent episode.

The next day the first patient's brother (case B) attended complaining of penile ulceration of three days' duration, which had been preceded by local irritation, malaise, and headache for four days. HSV was isolated, and antibody studies confirmed the diagnosis of primary genital HSV infection. All three patients gave negative serological test results for syphilis and had no concomitant genital infection. As the table shows, patients A and B had had sexual intercourse with other partners during the early phase of their infection while prodromal systemic symptoms and local redness and irritation were present, but before the onset of blistering and ulceration. Figure 1 shows the subsequent history of HSV infection in their sexual partners.

TABLE History of sexual intercourse of seven patients

Day	Event
0	Case B had sexual intercourse with case C
7	Case A had sexual intercourse with case C
12	Case A had sexual intercourse with case E Case B had sexual intercourse with case D
13	Case A had sexual intercourse with cases F and G
14	Case A attended clinic
15	Case C attended clinic
16	Case B attended clinic

FIG 1 Diagram of transmission of herpes simplex virus type 2 (HSV 2). (GP = general practitioner, STD = sexually transmitted diseases.)

We examined the DNA of the HSV isolates from patients A, B, and C using restriction endonuclease analysis as described previously.⁴ The viruses were identified as being type 2, and the electrophoretic profiles were identical when cleaved with the enzymes Bam H1, Xho 1 (fig 2), and Kpn 1 (results not shown).

The follow up of patients A and B provided interesting data. In the six months after diagnosis, A and B each had 10 recurrences: four of these began within five days of each other, a further two within seven days, and three more within 10 days. So far, two HSV 2 isolates from recurrent episodes in patient B have been examined by restriction enzyme analysis with Bam H1 (fig 2), Xho 1, and Kpn 1 (results not shown). DNA from both isolates was identical, in number and relative position of restriction enzyme cleavage sites, to DNA from the primary isolates of patients B and A and the cervical isolate from patient C. We did not find DNA fragments differing in their electrophoretic mobility, which is a feature of recurrent isolates of HSV.^{14,5}

Discussion

This case report raises several important points regarding genital HSV infection. Firstly, the value of contact tracing patient C and detecting the presence of asymptomatic cervical viral shedding was considerable. Mertz *et al* have argued that the identification and screening of such source contacts may reduce the transmission of the infection.⁶ Having been traced and identified as the source of the infection, however, this patient needed counselling on how to prevent further transmission of the disease. Our management began with an attempt to improve the awareness of her

symptoms during an HSV recurrence in which lesions were not visible. In a previous study we had found that asymptomatic shedding from the genital tract was associated with tender inguinal lymphadenopathy, vaginal discharge, and dysuria.⁷ Patient C was encouraged to return for examination and to have tests for the presence of HSV whenever she wished. In the six months after diagnosis she returned 12 times: on four occasions she was found to have bacterial vaginosis, and on two candidiasis. HSV was not isolated from her urethra, cervix, or vulva at any of these visits. Advice was also given to the patient regarding the value of barrier contraception, as HSV cannot penetrate a sheath.⁸ Furthermore, the possibility of antiviral drug treatment was discussed, particularly the use of prophylactic continuous oral acyclovir, which has been shown to prevent symptomatic recurrences.^{9,10} No data are available on the effect of this treatment on genital asymptomatic shedding, but a study using prophylactic acyclovir in immunocompromised patients reported oral asymptomatic shedding during treatment.¹¹ Patient C opted to wait until we had investigated her pattern of infectivity before any treatment was attempted.

Secondly, the transmission of genital HSV infection to four sexual contacts during the prodromal phase was an important feature in the transmission of the disease. Prevention of such transmission rests on improving health awareness and encouraging access to STD clinics, as well as on improving diagnostic techniques.

Thirdly, this case report offers an unusual opportunity to investigate the strain epidemiology and genome characteristics of a known virus during its transmission. Restriction enzyme analysis of viral DNA distinguishes unequivocally between HSV types 1 and 2 and characterises viruses within each serotype as being epidemiologically related or not by the presence or absence of restriction sites.¹² The site of latency in the nervous system has been thought to be occupiable by only the single virus that caused the primary infection.¹³ There is now good evidence that mixed populations of HSV showing strain differences (variations in the number of restriction sites) exist within ganglionic cells in the nervous system.¹⁴ Size heterogeneity of restriction fragments due to reiteration of sequences in certain regions of the viral genome without a change in the number or relative position of restriction sites characterises HSV subpopulations in cell culture.¹⁵ These minor differences can distinguish between HSV type 1¹⁶ or type 2^{4,5} isolates from successive episodic attacks. Together these findings provide evidence for virus heterogeneity in the latent form of HSV. Reactivation of subpopulations of low virulence may interrupt the transmission of more pathogenic forms of HSV. Alternatively, virus populations in the latent form, which are homogeneous, might

FIG 2 Electrophoretic profiles of DNA from type 2 reference virus (HG52), isolate from asymptomatic shedder (case C), primary isolates (A and B) from two brothers (cases A and B), and recurrent isolates (B₂ and B₃) from case B after digestion with *Bam* HI; and profiles of DNA from viruses A, B, and C, and herpes simplex virus type 1 (HSV 1) after digestion with *Xho* I.

be expected to maintain their inherent characteristics during reactivation and transmission.

The herpes simplex virus strain studied in this case report retained total identity by restriction enzyme analysis after transmission to two people, which resulted in concurrent infections, and during two episodes of reactivation in one patient. The efficiency of transmission of this virus seems to be high. The close

temporal relation of the onset of recrudescence in the brothers would be unlikely if only exogenous factors triggered recurrences. Each patient has a different occupation and lifestyle, and therefore endogenous characteristics of the virus probably exerted an important effect on the timing of recurrences. A more frequent rate of recurrence for HSV type 2 is well documented.¹⁷ If the characterisation of HSV by

analysis of viral DNA, viral proteins,¹³ or other features of virus growth eventually provide markers of virulence, such information will be useful both for counselling patients about prognosis and for planning management.

In conclusion we have shown that, though early tracing of source contacts of patients with genital HSV is of value, it does not prevent the transmission of HSV infection in the early phase of the disease. To help reduce the spread of this disease we need improved health education, faster diagnostic techniques, and further research into the patterns of asymptomatic shedding of HSV and the relation of DNA restriction endonuclease profiles to recurrent disease patterns.

We thank the Joint Standing Research Committee at St Mary's Hospital, London W2, for its support. We also thank Helen Brown for her help in preparing the manuscript. The molecular weights for the HG52 DNA fragments, and the virus, were kindly supplied by Dr Andrew Davison, Institute of Virology, Glasgow.
