MATTERS ARISING

The falling accuracy of microscopy in the diagnosis of gonorrhoea—a cause for concern?

Dr J K Evans and colleagues recently reported on the results of an audit into the value of microscopy in the diagnosis of gonorrhoea at a major London genitourinary medicine (GUM) clinic and illustrated the problems of the interpretation of the Gram-stained smear.1 Although the detection rate for gonorrhoea in male urethral specimens had a sensitivity of 69%, they demonstrated a significant decrease in the sensitivity of microscopy of endocervical smears for diagnosing gonorrhoea in women (29% in 1991, 70% in 1973) within their unit.2 Furthermore, they observed a drop in the sensitivity of the Gram-stained urethral smear for the detection of gonorrhoea in men from 89% to 76% on re-audit which suggests that there may be a problem with smear interpretation.

The authors assessed the value of microscopy in the diagnosis of culture-proven gonococcal infection in heterosexual men and women attending our GUM clinic over a one year period commencing in March 1992. The urethral smear in men detected 179 (89%) of 202 cases of culture-positive gonorrhoea. In total, Gram-stained smears for 141 women with culture-positive gonorrhoea were analysed. The endocervical smear detected 52% of 126 female patients with positive endocervical cultures and 40% of 101 female patients with positive urethral cultures. A combination of urethral and endocervical smear screening allowed 53% of all female patients with culture positive gonorrhoea to be diagnosed at first visit. The "blind swab" rectal smear detected only one of 25 female patients with culture-positive rectal gonorrhoea. Three patients (2%) had N gonorrhoeae isolated from the rectal site alone. Rectal site sampling is probably not a useful exercise except in patients at high risk of having gonorrhoea, such as contacts of known cases, and would merit further evaluation as the prevalence of gonorrhoea continues to fall in the United Kingdom. Proctoscopy has been shown to increase the sensitivity of anorectal smears in the evaluation of symptomatic male patients at risk of gonorrhoea compared to a blind swab technique3 although the sensitivity of culture is not improved.4 However, this method of rectal sampling may be unacceptable to female patients.

In large GUM clinics, where there is a continual change-over of personnel, it is essential that training should be given to new staff in the methods of specimen collection during the clinical examination. Meaningful and accurate laboratory results are dependant on obtaining good clinical specimens and poor sampling technique decreases the sensitivity of microscopy for the diagnosis of gonorrhoea.5 At our GUM clinic, the cervix is wiped with a large cotton-tipped Rolon swab before material is obtained. A loop from the endocervix for Gram staining and culture. Dr Evans and colleagues did observe a non-significant improvement in the sensitivity of endocervical smears adopting a similar approach.

Re-reading original slides in "slide negative" but culture positive cases is essential as these often represent the most difficult slides to interpret. Dr Evans' letter demonstrated that re-reading of "negative" slides by an experienced microbiologist in a non-clinic setting showed 64% were wrongly reported initially. This means storage facilities should be available to keep all patient slides for at least a week. Good communication between doctors and microbiopists is essential to highlight which slides are most likely to be positive to allow more time for selective slide-reading.

It is well recognised that the performance of any microbiological test decreases when the prevalence rate of the corresponding disease diminishes. The decreasing prevalence of gonorrhoea in the UK places even greater difficulty in ensuring that accuracy in slide-reading is kept at acceptable levels. A combination of continual staff training, regular audit of microscopy and collaboration between microbiology and GUM clinic staff with checking of presumptive negative and positive smears can result in an acceptable level of result if a high diagnostic standard is to be achieved.

Kaposi sarcoma in Germany

Albrecht et al's report of cases of Kaposi's sarcoma (KS) in HIV-infected women provides further substantial evidence, from the western hemisphere, for a putative sexually transmissible aetiologic agent of KS.1 Unlike previous reports which were based on data from homosexual men,2,3 their's suggest that the agent could be transmitted heterosexualy and, therefore, lends itself to comparison with experience from some parts of Africa where KS and HIV infection are both common in heterosexuals, separately and concurrently. Moreover, they imply that two of their patients, who were of African origin and had recently come from there, could have acquired the KS agent from Africa.

One of us has previously pointed out that the epidemiology of KS in Africa is not consistent with a sexually transmissible aetiology as suggested by Albrecht et al5 and other studies from western countries.6 We find the evidence for sexually transmissible aetiology generated from Western data quite appealing; and the disparity with African data very intriguing. It has been suggested that the fact that the African countries with a high incidence of HIV infection generally also have high incidence of KS; and that patients with AIDS-related KS and those with non-AIDS KS have comparable high risk factors for sexually transmitted infections, argues for a putative sexually transmissible aetiology for KS.5 However, the lack of concordance for KS among couples with AIDS-related and non-AIDS KS in Uganda7 and Zambian8 co-horts suggests for sexual transmission. A report of 10 cases and review of the literature. Genitourin Med 1994;70:394-8.
