A case cluster of possible tissue invasive gonorrhoea

I read with great interest the report by Brook et al of a cluster of five cases of invasive gonococcal infection. The authors apparently are unaware of a similar report published over twenty years ago. We described a cluster in which a male patient with gonorrhoea infected seven of eight female contacts. Two other female partners could not be located. Among the seven infected women, two had disseminated gonococcal infection, four had pelvic inflammatory disease, and one had a Bartholin gland abscess. Three weeks after successful treatment of his urethritis, the male index case returned with disseminated gonococcal infection, having resumed intercourse with some of the same partners prior to their diagnosis and treatment.

In 1973 we lacked the ability to definitively prove that all of our patients were infected with the same strain of Neisseria gonorrhoeae. However, the epidemiologic circumstances made it clear that most or all of the patients in fact shared a common source. We also cited several other reports from 1940 to 1972 that documented complications of gonococcal disease in couples or in mother-infant pairs. Collectively, these reports provided the first hint of variations in pathogenicity among gonococci. There is more new under the sun (to coin a phrase)!}

Pseudomonas aeruginosa infections and HIV

Ali, et al provide an interesting overview of their experience over a five year period with pseudomonas infections in HIV seropositive patients. Their report of an increase in the frequency of both pneumonic and septicaemic illness due to this organism concurs with other recent studies. Two points arise however, which merit further discussion. A report from this centre is incorrectly referred to as illustrating that pneumonias due to Staphylococcus aureus and nosocomially acquired gram-negative organisms occur with increased frequency in patients with indwelling central venous catheters (CVCs). In fact, what the quoted study demonstrated was an increased frequency of pseudomonas as an isolate in the blood cultures of HIV seropositive patients with septicemia (found in 19 of 52), especially those with indwelling CVCs, in only two of these patients was this due to Pseudomonas aeruginosa. In the same study an apparent association with concurrent CMV infection was cautiously suggested, but the results of Ali et al do not support this. More importantly however, their conclusion that the use of systemic ceftriaxone/ciprofloxacin was the cause probably is a myth.

Collectively, these studies have shown that the conclusion of systemic pneumocystis/cystis prophylaxis is an independent risk factor for the development of Pseudomonas aeruginosa pneumonia is erroneous and is not supported by the data of several studies. As the authors note, the affected patient group were all in the advanced stages of HIV disease with low CD4 counts. Not surprisingly therefore, the vast majority were also on Pneumocystis carinii prophylaxis. However, without showing an increased risk for this group over a similarly severely immunosuppressed matched group not taking PCP prophylaxis (which for obvious reasons would be difficult to gather), this conclusion cannot be drawn. The low CD4 count, on the other hand, may be the relevant variable.

Pneumococcal vaccine and HIV infection

Helberg and colleagues state "An association between cervical dyskaryosis, as well as the role of HPV in cervical cancer in situ and in invasive cancer, has been demonstrated." They quote Franceschi and colleagues in support of this claim. Sheppard and colleagues report the psychological distress of patients diagnosed with genital warts for whom "...there is the fear of the link between genital warts and cervical cancer". The paper which is frequently quoted as establishing a link between genital warts and cervical cancer by Franceschi and colleagues did not say such things. These authors studied women attending a gynaecological medicine clinic, who had smears taken. Among the women attending with genital warts there was a significant excess of smears showing "superficial dyskaryosis". None of these women had evidence of high grade CIN and certainly none of them had cervical cancer. All of the more severe cytological abnormalities occurred in women with trichomiasis and gonorrhoea.

Having performed this preliminary study, two of the authors returned to Italy where they conducted a more rigorous study, which demonstrated no evidence of an association between genital warts and subsequent cervical carcinoma in situ or invasive cervical cancer. Ever since discovering the second negative paper it has always amazed me how widely quoted is the first paper by these authors, whilst the second is almost universally ignored. Is it because the first paper was in a British journal and the second one in an American journal? Did the first paper have a "snappier title" Or was it because the first paper confirmed people's prejudices and the second didn't? The original myth of an association was further refuted by our own work.

Could it be that the myth of genital warts needs the same treatment as the other myth about cervical cancer—that it "has been around for 150 years now it must be true. It is true. It is in virgins"—finally debunked in 1991? 5

Carcinoma of the penis: A cluster of cases in young men

The authors of the recent article Carcinoma of the penis in a HIV positive patient 2 emphasise that this malignancy is rare in the immunocompetent population, especially among young men. Indeed, in 1989 (the most recent year for which figures are available) 3 there were only 45 notified cases in men under the age of 50 years in England and Wales. It may therefore be of interest to report that recently, in the space of seven months, no fewer than four apparently immunocompetent men presented to this department with ulcerating lesions, un抹y suspicious of malignancy. The men's ages ranged from 34 to 48 years. Although none had a HIV test, they were all heterosexual with no high risk factors for HIV infection. Two of the four had clinical appearances suggestive of lichen sclerosus, a third had a history of genital warts and all were uncircumcised.
