Nucleic acid amplification tests have the ability to specifically amplify small quantities of DNA and hence have been used successfully in the diagnosis of STDs. An in-house polymerase chain reaction (PCR) method was developed and evaluated for the detection of Neisseria gonorrhoeae DNA in the urogenital specimens collected (with consent) from patients visiting an STD clinic in India. The primers (forward primer 5’-CAACTATCCCCGGAGGCA-3’ and reverse primer 5’-GTATACAGCTTCGCCTGAA-3’) amplify the 221–480 bp region of orf1 gene. Clinical isolates (n = 40) of N. gonorrhoeae were recovered from urethral or cervical swabs by inoculation onto modified Thayer-Martin medium and identified by Gram stain, colony morphology, positive oxidase, and rapid carbohydrate utilisation test. For PCR the clinical samples (n = 489) were centrifuged (30 minutes, 14,000 g) and the cell pellet was lysed with 50 mM TRIS-HCl (pH 7.5) 1% Triton X-100, 1 mM EDTA, 250 μg of proteinase K per ml at 37°C for 1 hour, boiled for 10 minutes, and centrifuged. Eight μl of lysate was used for amplification (40 cycles) under standard conditions. Each cycle consisted of 30 seconds at 94°C, 30 seconds at 52°C, and 1 minute at 72°C. The amplified PCR product (10 μl) was analysed by electrophoresis in a 2% agarose gel and characterised by sequencing. An amplified product of 260 base pairs (bp) of orf1 gene was observed with all N. gonorrhoeae isolates but not when DNA from the other non-gonococcal strains (17 closely related Neisseria species, Corynebacterium, Chlamydia trachomatis, Candida, syphilis, and members of Enterobacteriaceae) was used as a template. For the 427 clinical swabs collected from men, 379 were positive and 46 were negative by both culture method and orf1-PCR assay. Urethral specimens from two men were culture negative but PCR positive for orf1 gene. Since these two samples tested PCR positive for orf1 gene of N. gonorrhoeae they were considered true positives. Thus, a total of 381 men (89%) were classified as true positives based on the PCR assay (table 1). Of the 62 women tested, 52 were true positives, and five were true negatives as they gave concordant results irrespective of the site of collection and the diagnostic method used (table 1). Four culture negative specimens tested positive by the PCR assays using primers specific to orf1 as well as cppB gene and were, therefore, considered positive. One culture negative specimen was positive by the orf1-PCR assay for its endocervical sample but negative for urethral specimens. For the cppB gene amplification, the specimen yielded a negative result for both the sites. This was therefore classified as true negative. The sensitivity, specificity, positive predictive value, and negative predictive value for the PCR method described here would be 100%, 98%, 100%, and 99.7%, and 100% respectively. The gold standard has been reported as having a sensitivity of 85–95%. The high specificity and sensitivity (25 fg DNA per assay, equivalent to 10 cells) coupled with low cost and rapidity of the in-house PCR assay described here can serve as a promising diagnostic method for the detection of gonococci directly from clinical swab samples.

### Detection of Neisseria gonorrhoeae by PCR using orf1 gene as target

Nucleic acid amplification tests have the ability to specifically amplify small quantities of DNA and hence have been used successfully in the diagnosis of STDs. An in-house polymerase chain reaction (PCR) method was developed and evaluated for the detection of Neisseria gonorrhoeae DNA in the urogenital specimens collected (with consent) from patients visiting an STD clinic in India. The primers (forward primer 5’-CAACTATCCCCGGAGGCA-3’ and reverse primer 5’-GTATACAGCTTCGCCTGAA-3’) amplify the 221–480 bp region of orf1 gene. Clinical isolates (n = 40) of N. gonorrhoeae were recovered from urethral or cervical swabs by inoculation onto modified Thayer-Martin medium and identified by Gram stain, colony morphology, positive oxidase, and rapid carbohydrate utilisation test. For PCR the clinical samples (n = 489) were centrifuged (30 minutes, 14,000 g) and the cell pellet was lysed with 50 mM TRIS-HCl (pH 7.5) 1% Triton X-100, 1 mM EDTA, 250 μg of proteinase K per ml at 37°C for 1 hour, boiled for 10 minutes, and centrifuged. Eight μl of lysate was used for amplification (40 cycles) under standard conditions. Each cycle consisted of 30 seconds at 94°C, 30 seconds at 52°C, and 1 minute at 72°C. The amplified PCR product (10 μl) was analysed by electrophoresis in a 2% agarose gel and characterised by sequencing. An amplified product of 260 base pairs (bp) of orf1 gene was observed with all N. gonorrhoeae isolates but not when DNA from the other non-gonococcal strains (17 closely related Neisseria species, Corynebacterium, Chlamydia trachomatis, Candida, syphilis, and members of Enterobacteriaceae) was used as a template. For the 427 clinical swabs collected from men, 379 were positive and 46 were negative by both culture method and orf1-PCR assay. Urethral specimens from two men were culture negative but PCR positive for orf1 gene. Since these two samples tested PCR positive for orf1 gene of N. gonorrhoeae they were considered true positives. Thus, a total of 381 men (89%) were classified as true positives based on the PCR assay (table 1). Of the 62 women tested, 52 were true positives, and five were true negatives as they gave concordant results irrespective of the site of collection and the diagnostic method used (table 1). Four culture negative specimens tested positive by the PCR assays using primers specific to orf1 as well as cppB gene and were, therefore, considered positive. One culture negative specimen was positive by the orf1-PCR assay for its endocervical sample but negative for urethral specimens. regimen (table 1). Inclusion of these patient charts in this study was approved by a research ethics committee at Bellevue Hospital. All patients received NVP + EFV at standard doses. The lower limit of quantitation was determined at 50 HIV RNA copies/ml using Roche AmpliCob H.1V-Monitor (RNA) (Roche Diagnostics, Branchburg, NJ, USA). Median baseline values were: viral load 33 900 copies/ml (range 3100–750 000 copies/ml) and CD4+ count 190 cells x10⁹/l (range 2–440 cells). After a median follow-up of 11 months (range 3–18 months), 85% (11/13) had viral loads < 50 copies/ml. Considering previous treatment experience, 90% (9/10) of NNRTI naive patients had viral loads <50 copies/ml and 67% (2/3) of NNRTI experienced patients had viral loads <50 copies/ml. Effectiveness of the dual NNRTI combination in heavily pretreated patients is in contrast with a study using a single NNRTI plus two NRTIs in NRTI experienced patients in whom rapid virological failure was observed. These results suggest that the combination of two potent NNRTIs may be able to overcome development of NNRTI associated resistance, even when there are only one or two NNRTIs in the combination. These data accord with those of Jordan and colleagues who demonstrated a sustained response to NVP + EFV in combination with only didanosine (ddI) in 19/21 patients after 12 months.* The most common adverse event was elevated liver function test results (more than three times upper limit of normal) in three patients. One case of liver toxicity was attributed to Bactrim, and a second case resolved three times upper limit of normal in three patients. The lower limit of quantitation was determined at 50 HIV RNA copies/ml using Roche AmpliCob H.1V-Monitor (RNA) (Roche Diagnostics, Branchburg, NJ, USA).

### Comparing cost effectiveness of screening women for *Chlamydia trachomatis* in systematic and opportunistic approaches

Screening women for asymptomatic *Chlamydia trachomatis* (CT) infections is indicated to prevent the spread of CT and the development of complications such as pelvic inflammatory disease (PID), chronic pelvic pain, ectopic pregnancy, tubal infertility, and neonatal pneumonia (major outcomes averted: MOA). Cost effectiveness presents an important aspect in the decision making regarding actual implementation. Recently, in this journal Van Valkengoed et al published a paper on the cost effectiveness of systematic screening among women in Amsterdam (Netherlands), using pharmacoeconomic modelling. "Using the same model, results on the cost effectiveness of an opportunistic screening in the same city have also been published." Specific model assumptions differed in both publications. The aim of this letter is to compare cost effectiveness of systematic and opportunistic screening using similar model assumptions and correcting for potential biases.

Opportunistic screening was done during May 1996 to May 1997 in a pilot study. Women visiting the participating GPs were eligible for screening if they considered themselves heterosexually active, were aged 15–40 years, and did not visit their GP for sexually transmitted disease complaints (participation among women: 96% compared with 50% in the systematic screening). In this letter we report on the age group 15–30. Obviously, the effectiveness of this type of screening depends on the frequency of visiting the GP, 87% of Dutch women aged 15–30 visit the GP at least once per year. As in the universal systematic screening, testing was done with ligase chain reaction (LCR) on urine. Participating GPs in the opportunistic screening had an over-representation compared to the general Amsterdam situation of participants from Caribbean, Surinam and other (source: Statistics Amsterdam).

Parameters in the pharmacoeconomic model were kept similar to the previous paper in this journal, except for the probability of PID after asymptomatic infection. For this probability we applied 20% compared to 10% in the paper by Van Valkengoed et al. We even consider 20% as a very conservative estimate for the risk of PID in our model. Cost effectiveness was estimated as net costs per MOA in baseline analysis using assumptions.
above and sensitivity analysis (PID risk at 10%, high performance testing and pooling). In the baseline analysis cost effectiveness is US$5300 per MOA for systematic screening of women aged 15–25 and $1400 for opportunistic screening of that age group. Including sensitivity analysis, cost effectiveness of systematic screening ranges from $2000–$11 100 per MOA (see table 1). For opportunistic screening this range is $500–$4100 per MOA. For the age group of 15–30, cost effectiveness is estimated to be generally slightly less favourable.

We conclude that opportunistic instead of systematic screening reduces net costs per MOA up to 75% (age groups 15–25) and by approximately 50% (age groups 15–30) over a range of plausible assumptions. Opportunistic CT screening in Amsterdam is therefore more attractive than systematic screening from a pharmacoeconomic point of view. Obviously, pharmacoeconomics only present one aspect in decision making concerning CT screening, others being, for example, implementation issues and budgetary constraints.

Major improvements in cost effectiveness of screening women for Chlamydia trachomatis using pooled urine specimens and high performance testing

Screening of asymptomatic Chlamydia trachomatis (CT) infections is indicated to prevent the spread of CT and the development of secondary complications like pelvic inflammatory disease, ectopic pregnancy, and tubal infertility. Cost effectiveness presents an important aspect in the decision making regarding actual implementation. A recent paper in this journal by Van Valkengoed et al. addressed cost effectiveness, using an established pharmacoeconomic model, of a systematic screening programme for asymptomatic CT infections in women registered in general practices in Amsterdam, based on mailed home obtained urine specimens. The aim of this letter is to extend the application of the pharmacoeconomic model with regard to pooling and improved test performances (sensitivity and specificity).

We recently determined the sensitivity and specificity for two commercially available CT detection assays for urine specimens from asymptptomatically CT infected women and men. In total, 2906 mailed home obtained urine specimens were tested for CT using both ligase chain reaction (LCR) and polymerase chain reaction (PCR) testing. We showed that for individual testing, the test sensitivity/specificity for LCR and PCR could be estimated at 78.6%/99.7% and 98.8%/99.9%, respectively. Furthermore, we recently showed by using individual urine samples (n = 650) and samples pooled by five (n = 130) that pooling has a relative sensitivity and specificity of 100%. Since only CT positive pools have to be analysed for the individual CT positive cases approximately 60% of the number of tests could be saved in our population with an estimated CT prevalence of 2–3%.

In the pharmacoeconomic model test performance of 85.0% sensitivity and 99.0% specificity were previously assumed. Furthermore, the model included population based estimates of CT prevalence, the costs of the programme, the health gain effects and the related monetary benefits. Health gain effects considered were averted pelvic inflammatory disease, chronic pelvic pain, ectopic pregnancy, infertility, and neonatal pneumonia (major outcomes averted; MOA). Both direct and indirect costs and benefits were considered. We investigated the effects on baseline cost effectiveness of pooling and improvements in test performance.

Population based prevalence in the systematic screening was 2.2% for women aged 15–40 and 2.9% for women aged 15–25. Van Valkengoed et al. estimated baseline cost effectiveness for systematic screening in Amsterdam using LCR at net costs of US$11 100 for women aged 15–25 and US$15 800 per MOA for women aged 15–40 (table 1). High performance testing of 98.8% sensitivity and 99.9% specificity was estimated to reduce net costs per MOA by approximately 20%. Pooling urine specimens by five was estimated to reduce net costs per MOA by 57%. A total decrease of 67%
was estimated if both high performance testing and pooling are assumed (table 1). We conclude that with pooling and application of high performance testing major improvements in cost effectiveness of screening women for asymptomatic CT can be obtained.

Anti-HIV serology in patients with sexual dysphoria in screening test before sex change surgery
The health and behavioural issues of homosexual men and women have recently become a focus of research and interest. A well conceived framework within which to consider the uniqueness of problems faced by homosexual youths and the role of healthcare providers is needed.1 Significant physical morbidity occurs among homosexual men and women because healthcare providers are often unaware of their actual or potential health concerns. Physical health concerns mainly include HIV disease, hepatitis, and other sexually transmitted diseases. Health-care professionals, who are clinically competent in the care of homosexual men and women, should have the opportunity to reduce the risk of disease, while providing unbiased, quality care which recognises the unique problems of this population.1 In this study, we report the prevalence of HIV infection among the homosexual men and women who visited the pre-admission clinic, King Chulalongkorn Memorial Hospital, Bangkok, for further sex change surgery.

A prospective study on the data concerning anti-HIV test for 35 cases (33 homosexual men and two lesbian women) with sexual dysphoria who attended the pre-admission clinic, King Chulalongkorn Memorial Hospital, Bangkok for further sex change surgery.

Table 1: Demographic data and anti-HIV serology

Asymptomatic Chlamydia trachomatis infections. The prevalence was equal to 5.71%. These two cases were homosexual. The demographic data of HIV seronegative and HIV seropositive cases are shown in table 1.

Currently, the two major routes of transmission of HIV are blood borne and sexual propagation. Sexual propagation also includes the abnormal sexual behaviour such as oral and anal sex found in the “gay” population.1 Unique aspects of Thai culture have shaped the response of homosexual men and women to HIV infection in Thailand. Thailand is a relatively homogeneous society that has, by and large, felt invulnerable to AIDS, viewing it primarily as a Western phenomenon. This attitude has also been common in the gay community and has resulted in some homosexual men and women engaging in high risk behaviour.

In Thailand it has been argued that HIV infection is still a major health problem among homosexual men and women. The current HIV epidemic among young homosexual men and women is a major public health concern. Nevertheless, hardly any specific HIV education interventions have been designed for this population. In this study, the rather high rate of HIV infection among the homosexual men and women attending the hospital for further sex change surgery was detected. Compared with the rate in the general population in Thailand,2 this rate is five times higher. Therefore, this population is still a target group for HIV infection, and thus, proper control for this population is necessary.

Neuropsychiatric reaction induced by clarithromycin
We read with interest the case report by Prime and French1 describing a person with HIV infection who developed a severe neuropsychiatric reaction during clarithromycin, zidovudine, didanosine, and nevirapine treatment. The authors suggest that this reaction was caused by the clarithromycin and not the antiretrovirals. Indeed, central nervous system (CNS) symptoms are a known side effect of clarithromycin.2 CNS adverse effects, however, have also been reported with zidovudine3 and efavirenz.4

So far with nevirapine neuropsychiatric side effects have not been described. For this reason we would like to report the case of a patient who developed CNS side effects shortly after starting nevirapine.

A 40 year old woman with HIV infection was initially treated with ritonavir, saquinavir, and stavudine. Because she developed lipodystrophy she was switched to nevirapine, lamivudine, and zidovudine. Shortly after starting this treatment, she started to feel depressed and to experience bad dreams. Her CD4+ lymphocyte count was 727 × 109/L and her viral load was undetectable. She was living under stressful conditions (her husband was also living with the HIV virus) and according to her there was no recent change in her life to explain this depression. The nevirapine was replaced by abacavir and from then on the CNS side effects rapidly disappeared.

This case report strongly suggests that the nevirapine was responsible for the CNS symptoms. CNS side effects related to antiviral treatment may be caused by high drug levels. Clarithromycin is known to increase nevirapine levels by about 26%.5 The fact that in the patient described by Prime and French the neuropsychiatric symptoms disappeared within 72 hours after stopping the clarithromycin suggests this drug was responsible for

References

Website: www.sextransinf.com

www.sextransinf.com
causing these symptoms. However, it is also possible that after stopping the clarithromycin the nevirapine levels decreased and that therefore potential nevirapine related side effects disappeared. We propose that in HIV clinical trials patients should be monitored more closely for possible neuropsychiatric side effects and that if these side effects appear antiretroviral drug levels should be measured.

Immune reconstitution eosinophilia due to schistosomiasis

A 21 year old black African heterosexually active, formerly resident in south east Africa, presented in early October 2000 on arrival in the United Kingdom. Examination revealed hepatosplenomegaly. Investigation showed Haemoglobin was 10.2 g/dl, WBC was 2.9 × 10^9/l (neutrophils = 1.5, lymphocytes = 0.8, and eosinophils = 0.3 × 10^9/l). Liver and electrolytes were normal. Liver function tests showed alkaline phosphatase = 1704 (normal = 45–122) IU/l, and alanine transaminase = 65 (normal = 7–63) IU/l. Hepatitis A and C serology was negative; hepatitis B serology showed IgG negative and IgM positive. Serum α fetoprotein was negative. An HIV-1 antibody test was positive, plasma HIV-1 RNA level had fallen to 25 000 copies/ml, CD4 count remained at 170 cells × 10^9/l but the eosinophil count had risen to 0.8 × 10^9/l (normal = 0.04–0.44 × 10^9/l). After 4 months of HAART the level of detection, the CD4 count had risen to 230 cells × 10^9/l and the eosinophil count had further risen to 1.3 × 10^9/l. At this time the patient agreed to treatment of schistosomiasis with praziquantel (40 mg/kg in two divided doses in 1 day). Following praziquantel the eosinophil count fell to 0.5 × 10^9/l. The development of eosinophilia in this HIV infected patient with schistosomiasis occurred in the context of a falling HIV RNA level and an increase of CD4 count, indicating partial immune reconstitution.

Partial restoration of cell mediated immunity induced by antiretroviral therapy, as demonstrated by recovery of partial CD4+ T lymphocyte reaction to memory antigens, may cause development of an inflammatory response, in this case eosinophilia, in patients latently affected with opportunistic and non-opportunistic pathogens. Reactivation of mycobacterial lymphadenitis, cryptococcal meningitis, and cytomegalovirus retinitis and pneumonitis have been described. The case described here suggests that development of an eosinophilia to schistosomiasis should be added to the list of immune reconstitution phenomena.

Absent for publication 13 December 2001

Cost effectiveness analysis of a population based screening programme for asymptomatic Chlamydia trachomatis infection in women

With reference to the article by van Valkengoed et al., we would like to express our views.

We agree with the authors’ statement that systematic screening of all women aged 15–40 years for asymptomatic Chlamydia trachomatis infection is not cost effective, especially when the prevalence of infection in Amsterdam is low (2.2–2.8%). Not all countries have achieved such low levels. Even in England and Wales where the prevalence of the infection is higher it is not cost effective to screen all women. However, computer modelling performed for the chief medical officer’s expert advisory group on Chlamydia trachomatis in the United Kingdom and other countries has shown that it is cost effective to screen populations where the prevalence is 3%–6%. The Chlamydia Pilot Study, which was conducted in Wirral and Portsmouth in 1999–2000, detected a prevalence of chlamydial infection of approximately 10% in women aged between 16 and 25. There is, therefore, a strong argument for screening this age group in the United Kingdom at the present time and not above 25 years as prevalence above this age is low.

One must be careful when extrapolating data from a different country with a different population. However, it would be wise to consider that in the future in the United Kingdom, when screening is established, the prevalence may fall and the cost effectiveness may be reduced.

Although it is not cost effective to screen men, as there are only minor sequelae to be prevented, one shouldn’t forget that they are the major reservoir of infection. We should aim not to reinforce existing inequalities by sparing them their share of responsibility for sexual health. Screening men will not only decrease the prevalence but also reduce the psychosocial impact of screening for genital chlamydia in women.
