**HIV tests in young adolescents attending a GUM clinic**

A pretest counselling session is recommended by the General Medical Council before attending a GUM clinic can have an HIV test without parental consent. A recent survey in the United Kingdom showed that 79% of clinics were prepared to test for HIV infection in children under the age of 16.1 We reviewed the characteristics of adolescents between the ages of 13 and 16 seen in the Coventry genitourinary medicine (GUM) clinic for an HIV test between 1990 and 2000 (table 1). This was part of a larger review of GUM attendances by children, the results of which have been published.2

The commonest mode of presentation was a specific request for an HIV test. This was the case in 32 (39.0%) adolescents. Eighteen adolescents (22.0%) coming in requesting a check up were also offered an HIV test, 22 (26.8%) alleged rape/assault, 14 (17.1%) complained of a discharge, and four (4.9%) had a needle-stick injury.

Ten (12.2%) of the adolescents seen had a sexually transmitted infection diagnosed (eight girls (11.4%) versus two boys (16.7%); p=0.6). Genital chlamydial infection was diagnosed in five cases, gonorrhoea in two cases, and there was one case each of genital herpes, *Trichomonas vaginalis*, and genital wart infection. Having a sexually transmitted infection diagnosed was associated with complaining of a discharge (12.5% versus 50.0% p=0.003) and prostitution (1.4% versus 20.0% p=0.03) but not with any other presenting complaint.

Adolescents coming in specifically requesting an HIV test were more likely to accept it following counselling than those who did not (96.9% versus 78.0%, p=0.02). Acceptance of HIV test was, however, unrelated to the sex of child, prostitution, more than one partner in the previous year, or being diagnosed with a sexually transmitted infection. There was no statistically significant difference between those claiming rape/assault and those who were not in having an HIV test after counselling (95.5% versus 96.9%, p=0.95).

There is no specific literature regarding the factors associated with HIV testing in young adolescents. A study of sexually active 16–19 year olds in Malaysia found that infrequent condom use and a history of sexually transmitted disease were not significantly associated with voluntary HIV testing.3 Hav- ing had more than one sexual partner in the past year and discussing HIV/AIDS with a doctor were however associated with voluntary HIV testing.4

It has been shown that most adolescents engaging in high or moderate HIV risk behaviour continued to do so into young adulthood.5 Knowledge about HIV infection and its prevention, estimates of personal risk or exposure to HIV programming content and approaches.6 must therefore be directed at research into adolescent risk behaviour change.

Sexual and reproductive health among female adolescents: preliminary results

The recognition of adolescence as an essential formative stage of life has implications for programming content and approaches.7 Young people have to be treated as people in their own right, and their individual needs considered on a case to case basis. The realisation that this is a time of significant and rapid change highlights the urgency to deal directly with sensitive topics such as sex and drugs.8

The aim of this study was to identify demographic, behavioural and clinical factors for STI and unplanned pregnancy among female adolescents assisted by the family health programme (PSF) of Vitória Municipality in Brazil. A cross sectional study was performed among female adolescents (15–19 years old) assisted by the PSF. Participants were screened for Chlamydia trachomatis and Neisseria gonorrhoeae using ligase chain reaction (LCR) applied to urine and answered a face to face questionnaire. Standard descriptive statistical analysis was performed. Prevalence rates were calculated to reflect the relative frequency of each disease, with corresponding confidence intervals (CI). The national school of public health (FIOCRUZ) ethics committee approved this study. Written, informed consent was obtained by all participants and their parents. The study included 149 adolescents. Mean age was 17.2 (SD 1.5) years; mean education was 8.3 (SD 2.9) years of schooling, and the mean age of the first sexual intercourse was 15.4 (SD 1.6) years. Seventy per cent of adolescents had already had sexual intercourse. Among those the prevalence rate of CT was 11.4% (95% CI 7.6 to 14.4), 4.0% (95% CI 2.1 to 5.2) of GC. Behaviour and clinical data are reported in table 1. There was statistical significance between chlamydia infection and previous STI (OR = 20.1, 95% CI: 5.9 to 67.9); gonorrhoea and no condom use (OR = 1.2, 95% CI: 1.06 to 1.12); and gonorrhoea and alcohol abuse (OR = 1.3, 95% CI: 1.1 to 2.1). Clinical problems identified were genital ulcer 6.0%, dysuria 15.4%, inguinal lymphadenopathy 12.1%, vagi- nal bleeding 3.4%, and pelvis pain 5.2%

STIs deserve attention not only because of their high prevalence but also because they frequently go undetected and untreated, and often result in serious sequelae and associ- ation with HIV infection.9 High prevalence rates associated with high frequency of risk were observed in this ongoing study. These two factors identify female adolescents as an important group to reach with STI including HIV prevention efforts.

These data are descriptive and need to be completed but they are in agreement with the last research about Brazilian sexuality. It was reported that adolescents have their first intercourse earlier than the older generation and the knowledge about STI/AIDS does not modify the exposition.10 Eighteen per cent of adolescents in Brazil become pregnant at least once and 54.1% among the married ones use some method of contraception.11 The preliminary results suggest that humane, healthcare based, STI/HIV prevention services in this health family programme can be an accept- able intervention, as well as one that is highly targeted epidemiologically. Screening, treat- ment and prevention counselling, and sup- port in communities should be considered...
Given this rise, we investigated whether our practice of co-treatment was of continued benefit. We therefore investigated whether our practice of co-treatment was of continued benefit. We and evaluated as a core component of STI/HIV prevention efforts in many or most places where STIs are public health problems.

Factors affecting co-infection with genital chlamydia and genital gonorrhoea in an urban genitourinary medicine clinic

Co-treatment for chlamydia is common practice when gonorrhoea is diagnosed in a UK genitourinary medicine setting. In Glasgow, the incidence of gonorrhoea across the city has tripled from 1995 to 2000.1 Given this rise, we investigated whether our practice of co-treatment was of continued benefit. We examined all patients presenting to the Glasgow Royal Infirmary Genitourinary Medicine (GUM) Service (including the Steve Retson Project service for gay men) between 1 April 1997 and 30 September 2000 who had genital gonorrhoea diagnosed on routine culture. We diagnosed genital chlamydia co-infection by ligase chain reaction (LCR) on first pass urine (for men) or endocervical swab (for women). We co-infected gonorrhoea in 351 attenders (287 men, 64 women), of whom 86 (25%; 95% CI 20% to 29%) were co-infected. Co-infection was significantly more common in women than men (294/488 (64%) v 57/287 (20%); p = 0.02). Homosexual or bisexually were significantly less likely to be co-infected than heterosexual men (15/134 (11.0%) v 42/135 (30%); p = 0.001). Co-infection became less common with increasing age (15–19 years 43%; 20–24 years 34%; >24 years 18%; χ² for trend = 15.4; p <0.0001) (see table w1 on STI website). Logistic regression modelling showed young age and female sex is to be independent predictors of co-infection, while homo/bisexuality was protective (see table w2 on STI website).

We recommend continuing co-treatment for chlamydia in all women and heterosexual men presenting with gonorrhoea in our setting. However, in common with other recent findings, co-infection with genital chlamydia is uncommon in male homosexual or bisexual attenders with genital gonorrhoea, and co-treatment may not be necessary in this group.

Screening for STIs in individuals with HIV infection

In Australia, Victoria has seen an increase in new HIV cases from 1999 to 2000, and this rise has been sustained in 2001. The rise primarily involves men who have sex with men (MSM), where rates of unprotected anal intercourse and bacterial sexually transmitted infections (STIs) have also increased.1 As bacterial STIs enhance HIV transmission,2 screening for asymptomatic infections may reduce the incidence of HIV.

A sexual health service in Melbourne reviewed medical records of MSM clients with HIV infection. This was conducted to determine how commonly STI screening of asymptomatic clients is performed and the proportion with bacterial STIs. At the sexual health clinic the records of MSM with HIV care primarily at that clinic between 10 January 2001 and 1 March 2002 were reviewed. Any record of bacterial STI screening in the last year, the anatomical sites screened, and the laboratory results of screening were collected on printed forms. At the Alfred hospital a pilot programme screening asymptomatic clients with HIV (n = 40) was undertaken in the outpatient department between 30 October 2001 and 4 December 2001.

Of the 66 sexual health clinic records fulfilling the criteria, 22 (33%) had screening for bacterial STIs, and eight were tested at all anatomical sites of infection (urethra, rectum, throat). Of the 22 tested, three (14%) tested positive for Neisseria gonorrhoeae (NG) by culture and/or Chlamydia trachomatis (CT) by ligase chain reaction (LCR). Three had rectal infection (NG = 2, CT = 3), two also had pharyngeal infection (NG = 2), and one also had urethral infection (CT = 1). At the Alfred Hospital 40 clients had swabs taken from all sites. Of these 40, eight (20%) HIV infected clients had rectal NG detected by polymerase chain reaction (PCR) with confirmatory assay.

We identified a relatively high proportion of infections in those screened—11 positive of the 62 tested (18%, 95% CI 9% to 30%). These findings do not mean that these individuals have been placing others at risk of HIV transmission because STIs may be acquired from unprotected sexual contact with other HIV infected individuals, or through sexual contact that is low risk for HIV transmission. Nevertheless, it would seem prudent to reduce the prevalence of STIs by making screening a routine part of the management of MSM. In the United States STI screening is recommended,3 and screening of MSM is also recommended in the draft “STI management guidelines for priority populations” from the Australasian College of Sexual Health Physicians (Chris Bourne, personal communication).

Four layer discontinuous gradient for HIV

Artificial innervation using processed semen is a risk reduction option, if they want children, for serodiscordant couples in whom the man is HIV positive. The main aim of this study was to develop a single semen processing technique to reduce HIV transmission risk to HIV negative wives without infection and to obtain better quality sperm.

Methods

After ethics committee approval and written informed consent, normozoospermic semen was provided by two asymptomatic HIV carriers. Discontinuous four layer density gradient, was provided by two asymptomatic HIV carriers. Normozoospermic semen was referred by the Ethics Committee and carrier's PBL. Centrifugation at 400 × g for 30 minutes. The specimens of each fraction were extracted to determine sperm quality and to detect HIV RNA and proviral DNA after 4 weeks of co-cultivation with each fraction and carrier's PBL. HIV p24 antigen was detected from Fr 2 or Fr 3 (tables 1 and 2). The percentage collection of sperm from Fr 1, Fr 2, Fr 3, and Fr 4 was 3 (2%), 32 (9%), 19 (8%), and 10% (4%), respectively. Motility rate was 55% (19%), 94% (4%), 57% (25%), and 19% (11%), respectively. HIV p24 antigen and proviral DNA after co-cultivation with each fraction were determined by indirect immunofluorescence assay and polymerase chain reaction (PCR), respectively.

Results

The percentage collection of sperm from Fr 1, Fr 2, Fr 3, and Fr 4 was 3% (SD 2%), 32% (9%), 19% (8%), and 10% (4%), respectively. Motility rate was 55% (19%), 94% (4%), 57% (25%), and 19% (11%), respectively. HIV p24 antigen and proviral DNA after co-cultivation with each fraction were determined by indirect immunofluorescence assay and polymerase chain reaction (PCR), respectively.

PBL = peripheral blood lymphocytes.

Discussion

HIV discordant couples have a risk of transmission generally if they wish to have a baby.1 Semprini et al2 reported continuous gradient centrifugation followed by a swim up procedure, and Marina et al3 carried out a similar method but HIV was detected in 5.6% of 107 samples. However, the condition of the sperm, after these processes, was not always sufficient for intruterine insemination.

We have developed a novel semen single processing technique to reduce HIV RNA and HIV proviral DNA to undetectable levels in the fraction whose sperm motility rate is higher than others. Furthermore, this fraction was confirmed to have no HIV infectivity in vitro. This method appears to be an attractive alternative for HIV discordant couples.

Erythema nodosum induced by chancroid

Erythema nodosum is a type of panniculitis which is often regarded as a complex reaction pattern to various aetiological factors of infective and non-infective origin.1 Infective agents outnumber inflammatory causes and drugs in causation of erythema nodosum in the developing countries. Almost all the infective agents including aerobic and anaerobic bacteria, viruses, fungi, parasites and mycobacteria can induce eruption of erythema nodosum.2 Among sexually transmitted infections lymphogranuloma venereum has been known to be associated with erythema nodosum not infrequently.3

A 23 year old woman presented with genital ulcer disease and painful rash over the legs of 1 week’s duration. There was no history of trauma, fever, or drug intake. She had a single stable exudate was observed. The abscess was uninfected. Examination revealed a single, 1–1.5 cm, irregular tender ulcer on the right labia minora with undermined margins and blisters on the top. The regional lymph nodes were firm, moderately enlarged, and tender. Speculum and vaginal examination was normal. Examination of the perianal region, perineum, and other mucosae was also normal.

Multiple tender, erythematous nodules subcutaneous lesions with dusky erythema were present over both shins, calves, and ankle joints. Investigations revealed a normal complete blood count, serum biochemistry, urinalysis and blood sugar. VDRL, HIV-1 ELISA, and HBsAg were negative. Dark ground illumination, smears, and cultures from the ulcer did not reveal aetiological diagnosis. Histopathology from the ulcer revealed an ulcerated surface with necrosis and neutrophilic infiltrate deeper to which a zone of new blood vessel formation with marked endothelial proliferation and a lymphoplasmacytic infiltrate was observed. These features were consistent with diagnosis of chancroid while histopathology of leg lesions confirmed it to be septal panniculitis consistent with a diagnosis of erythema nodosum. The ulcer was treated with erythromycin stearate 500 mg hourly for 7 days. The genital ulcer healed completely in 7–10 days but the lesions of erythema nodosum subsided completely in 5–7 days without any other treatment.

Erythema nodosum as a cutaneous reaction pattern was first observed by Willan in 1798.4 A female preponderance with a ratio of 3:1 is often observed in adults compared to an equal incidence at prepubertal age. Although the exact pathogenesis of erythema nodosum is not known, it has been regarded as a immune complex, deposition disease which prefers the richly supplied vascular adipose tissue of the legs. In the present patient the erythema nodosum and chancroid had a strong temporal correlation as erythema nodosum immediately followed the appearance of the chancroid and resolved completely with its resolution. Although erythema nodosum is known to be associated with innumerable infective agents, to the best of our knowledge chancroid leading to causation of erythema nodosum has not been observed before.
Gonococcal perianal abscess: re-emergence after cessation of co-trimoxazole

We report a case of perianal abscess due to Neisseria gonorrhoeae, which appears to have been suppressed but not eradicated by chronic low dose co-trimoxazole for a period of almost 6 months between acquisition and diagnosis. The patient was a 34 year old HIV infected homosexual man treated with didanosine, stavudine, and nevirapine with a HIV viral load of 500 copies per ml and a CD4 lymphocyte count of 280 × 10⁹/l. He was taking co-trimoxazole 400 mg/80 mg once daily to prevent Pneumocystis carinii pneumonia (PCP).

He reported last having receptive anal sex in June 2000. This was unprotected, with a casual partner at a “gay” sauna. Three weeks later he reported a perianal abscess which discharged spontaneously, requiring dressings for a few days. A sinus was observed and he was booked for elective surgery. He remained well for 5 months.

Co-trimoxazole PCP prophylaxis was stopped in November 2000 as his CD4 T lymphocyte count fell to 280 cell/mm3. Co-trimoxazole PCP prophylaxis was stopped. The likely explanation is that the faecal flora was not eradicated by the co-trimoxazole.

BOOK REVIEW

Not many books nowadays try to summarise the broad field of HIV and AIDS. This British Medical Bulletin does attempt to do that, in line with its usual approach to providing substantial coverage of health subjects, but with suitable depth as well as breadth. The last (and first) British Medical Bulletin on this subject was published in 1988. It covered quite similar topics, but the main change is the depth of knowledge.

Although the title of this volume reflects the general sense that the face of the pandemic has indeed changed in many ways—not least the global spread, and the impact of antiretroviral therapies where they are available—the overwhelming impression I had was how similar are the issues and perspectives it covers. This is partly a reflection of the extraordinary hothouse atmosphere of the early pioneering years, when we climbed the steep part of the learning curve with unparalleled speed. The subsequent years have been ones of consolidation, during which the detail has been explored and the basic ideas refined. This book reflects that, where the change in the face is in part a shift from an impressionistic image to a more fully representational portrait, evidently from the same original.

The chapters provide a balanced and compact, yet thorough, assessment of the main issues. The authors are active in the field; they have an appropriately British background for this series, yet their perspective is unequivocally global. The accounts are worthy, reliable, and authoritative. If there is a drawback it is conveyed the impression that they are rather dull to read, that was indeed my feeling. There was generally and disappointingly little sparkle or originality in the concepts or the writing. Where there was, it derived from a narrow focus on a small part of the canvas rather than any broader insight.

Who will use this volume? I would recommend it as a reliable and thorough review for a new entrant to the field. Some of the chapters are an excellent springboard for detailed exploration of their topic. But those who already work on HIV/AIDS will find little to engage or excite them. They would probably feel, as I did, that the fascinating wider changes in the actual face of HIV/AIDS, which are palpable in their work, have scarcely been touched upon.
