South Africa is in the midst of a catastrophic AIDS epidemic, with between 11% and 20% of South African adults HIV infected, 420 000 children orphaned by AIDS, and 1500 new HIV infections each day. To help slow the spread of HIV, the South African government and international aid organisations are investing significant prevention resources in voluntary counselling and testing (VCT). The South African government has established more than 450 VCT centres with more than 800 counsellors around the country. Research conducted in developed and developing countries has shown that VCT can reduce high risk sexual practices and can decrease rates of sexually transmitted infections. In addition, VCT is necessary for directing HIV infected people to antiretroviral therapy, which is becoming increasingly available in South Africa.

Only a fraction of South Africans at risk for HIV have undergone VCT. Although most South Africans are aware that VCT services are available, only one in five people in South Africa who know about VCT have been tested for HIV. Among the reasons that South Africans may not seek HIV testing are negative perceptions of testing services. Of men who were unaware of their HIV status indicated that AIDS related stigmas were an important factor in their testing decisions. More recently, Herek et al found that 38% of a US national sample of adults stated that they would be very concerned about stigma if they tested HIV positive, and 44% of people who expressed this concern indicated that stigma influences their testing decisions. In South Africa, AIDS related stigmas are also socially and culturally pervasive. In a South African national survey, 26% of respondents would not be willing to share a meal with a person living with AIDS, 18% were unwilling to sleep in the same room with someone with AIDS, and 6% would not talk to a person they knew to have AIDS. Stigmas may therefore pose considerable barriers to seeking VCT in South Africa. To our knowledge, the degree to which AIDS stigmatising beliefs are related to HIV testing in South Africa has not been reported.

This study examined social and cognitive factors that may influence health decisions in relation to HIV testing history in South Africa. A multivenuce community sampling strategy was used to obtain a cross sectional sample of South Africans residing in a black township in Cape Town. The study focused on comparing individuals who had been tested for HIV with individuals who had not yet been tested on measures of (a) HIV prevention knowledge, (b) HIV testing attitudes, and (c) AIDS stigmas. Comparisons were also made between people who knew their HIV test results and individuals who tested but did not know their results. The selection of social cognitive factors related to testing examined in this study was guided by the information-motivation-behavioural skills model of health behaviour, which posits that information (knowledge) and motivation (attitudes and beliefs) are critical in influencing HIV testing decisions. Accordingly, misinformation about AIDS, HIV testing attitudes, and AIDS

**Objectives:** A cornerstone of HIV prevention in South Africa is voluntary HIV antibody counselling and testing (VCT), but only one in five South Africans aware of VCT have been tested. This study examined the relation between HIV testing history, attitudes towards testing, and AIDS stigmas.

**Methods:** Men (n = 224) and women (n = 276) living in a black township in Cape Town completed venue intercept surveys; 98% were black, 74% age 35 or younger.

**Results:** 47% of participants had been tested for HIV. Risks for exposure to HIV were high and comparable among people tested and not tested. Comparisons on attitudes toward VCT, controlling for demographics and survey venue, showed that individuals who had not been tested for HIV and those tested but who did not know their results held significantly more negative testing attitudes than individuals who were tested, particularly people who knew their test results. Compared to people who had been tested, individuals who were not tested for HIV demonstrated significantly greater AIDS related stigmas; ascribing greater shame, guilt, and social disapproval to people living with HIV. Knowing test results among those tested was not related to stigmatising beliefs.

**Conclusions:** Efforts to promote VCT in South Africa require education about the benefits of testing and, perhaps more important, reductions in stigmatising attitudes towards people living with AIDS. Structural and social marketing interventions that aim to reduce AIDS stigmas will probably decrease resistance to seeking VCT.
stigmatising beliefs represent potential barriers to seeking HIV testing10 13 and were the focus of the current study.

METHODS
Participants and setting
Participants were 224 men and 276 women living in a black township in Cape Town, South Africa. The median age range was 21 to 25 years, 67% of participants were married, 52% completed high school, and 61% were not employed (see table 1). Participants were recruited from multiple venues in a township located within 50 miles of Cape Town. The Western Cape has an estimated HIV prevalence of 10.7% and the majority of HIV infections in the Western Cape occur in townships. The township that participated in the current study has a population of over 100 000, with a median monthly household income of 384 South African rands ($US42) and a median of five people per household.

Measures
Participants completed anonymous self administered surveys at multiple community venues. Surveys were administered in English and Xhosa. Measures included demographic characteristics, HIV testing history, HIV risk behaviour history, HIV prevention knowledge, HIV testing attitudes, and AIDS stigmas.

Demographic characteristics
Participants were asked their sex, age, years of education completed, employment status, marital status, and race.

HIV testing history
The survey included questions concerning history of HIV antibody testing. These measures were used to classify participants into groups based on whether they had been tested for HIV. Participants who reported having been tested for HIV indicated the results of their most recent test as positive, negative, or that they did not know the results.

HIV risk behaviour history
To assess HIV risk history, participants indicated the number of sex partners they had in the previous 3 months, whether they had ever exchanged sex for money or other survival needs, received a sexually transmitted infection (STI) diagnosis, had a genital ulcer, injected drugs, or had an injection drug using sex partner, and whether they had ever used a condom. All responses were dichotomous indicating the occurrence or non-occurrence of each risk factor.

HIV prevention knowledge
A 12 item test was used to assess HIV risk and prevention related knowledge. Items were adapted from a measure reported by Carey and Schroder14 and reflected information about HIV transmission, condom use, and AIDS related knowledge and were responded to as yes, no, or don’t know (see table 2 for knowledge items). The AIDS knowledge test was scored for the number of correct responses, with don’t know responses scored incorrect. The AIDS knowledge test was internally consistent, alpha = 0.70.

HIV testing attitudes
Participants responded to five HIV testing attitude items. The items were adapted from previous research on HIV testing and testing attitudes.15 Two items reflected positive outcomes from testing, two assessed adverse outcomes, and one item reflected HIV testing avoidance (see table 3). Items were responded to dichotomously, as either agree or disagree.

AIDS stigmas
Thirteen AIDS stigma items were adapted from previous research and developed for use in South Africa.15 The AIDS stigma items reflected negative beliefs about people living with AIDS (for example, dirty, cursed, untrustworthy),

*OR = odds ratios for people tested for HIV compared to people not tested; †OR = odds ratios for comparisons of people who have been tested with known results to people tested with unknown results; All odds ratios adjusted for age, years of education, sex, and survey venue; p<0.01; p<0.05; ‡reported for the past 3 months.
In addition, participants selected because of their potential associations with risk behaviours, age, education, sex, and survey venue. These covariates were included in multiple logistic regression analyses, adjusted for participant knowledge, HIV testing attitudes, and AIDS stigmas using characteristics, HIV risk behaviour history, HIV prevention knowledge, HIV testing attitudes, and AIDS stigmas. Comparisons of people who had been tested with those who were not tested for HIV on demographic characteristics indicated that individuals who had been tested had significantly more years of education than people not tested, although the difference between means was less than one year of education (see Table 1). No other significant differences in demographic characteristics were found between people who had been tested for HIV and people who had not been tested. Among participants who were tested there were no differences in demographic characteristics between individuals who knew their HIV test results and those who did not know their results.

**RESULTS**

**HIV testing history**

Results showed that 222 (44%) participants indicated that they had been tested for HIV, 266 (53%) had not been tested, and 12 (3%) refused to respond whether they had been tested for HIV. Most participants who were tested for HIV had been tested once (33%), twice (29%), or at least three times (19%). Of people who had been tested, 117 (53%) reported that they were HIV negative at their most recent test, 19 (9%) were HIV positive, and 86 (38%) did not learn the results of their HIV test. Comparisons of participants who had been tested and were not HIV positive (n = 203) with those who were not tested for HIV (n = 266) on demographic characteristics indicated that individuals who had been tested had significantly more years of education than people not tested, although the difference between means was less than one year of education (see Table 1). No other significant differences in demographic characteristics were found between people who had been tested for HIV and people who had not been tested. Among participants who were tested there were no differences in demographic characteristics between individuals who knew their HIV test results and those who did not know their results.

**HIV risk behaviours**

Comparisons of individuals who had been tested for HIV and those not tested for HIV on risk behaviour history variables are shown in Table 1. Risk factors for HIV were generally high and for the most part comparable between the two testing groups. Over 40% of both groups had two or more sex partners in the previous 3 months. More than 10% of participants had traded sex to meet survival needs, 35%
AIDS stigma and testing in South Africa

had had an STI, and 13% had a history of genital ulcers. Analyses showed that people who were not tested for HIV were more likely to have never used a condom and were more likely to have used injection drugs, both indicating potential higher risk among untested participants. Participants who had been tested were, however, significantly more likely to have been diagnosed with an STI. Taken together, 69% of those who had been tested indicated at least one of seven HIV risk factors (excluding never having used a condom), as did 62% of those who had not been tested, a non-significant difference. Among people who had been tested, those who did not know their test results were significantly more likely to have received and given money or food for sex, suggesting that people involved in sex trade were less likely to know their HIV test results.

**HIV-AIDS prevention knowledge**
Across all participants, AIDS knowledge was generally high; mean score on the knowledge test was 83% correct for the sample (see table 2). However, there was evidence of important misinformation in the context of this relatively high knowledge base. Items that were most frequently answered incorrect were “Must a person have many different partners to get AIDS?” 26%; “Is AIDS caused by spirits or supernatural forces?” 43%; “Does washing after sex help protect against AIDS?” 24%; and “Is there a cure for AIDS?” 24%. Comparisons between individuals who had been and had not been tested for HIV showed that groups did not differ significantly on HIV knowledge test scores, adjusted OR = 0.49, 95% CI = 0.15 to 1.58, and there were no significant group differences on any of the individual knowledge items. There were also no differences between people who knew their HIV test results and people who did not know their results in AIDS knowledge, adjusted OR = 0.95, 95% CI = 0.81 to 1.1.

**Attitudes toward HIV testing**
Comparisons between HIV testing history groups on attitudes towards HIV testing showed that participants who had not been tested held significantly more negative HIV testing attitudes than participants who had been tested after controlling for age, sex, education, and survey venue. Individuals who had not been tested for HIV were significantly less likely to view beneficial outcomes from testing, more likely to perceive adverse testing outcomes, and more likely to endorse test avoidance (see table 3).

Among people who had been tested, individuals who did not know their HIV test results demonstrated significantly more negative attitudes towards testing than those who knew their test results. These findings mirror the results of comparisons between people tested and not tested for HIV. Participants who did not know their test results were less likely to endorse benefits and were more likely to endorse adverse outcomes from testing.

**AIDS stigmas**
Results showed that individuals who had not been tested for HIV held significantly greater AIDS related stigmas than individuals who had been tested. People who had not been tested were significantly more likely to agree that people with AIDS are dirty, should feel ashamed, and should feel guilty. Participants who were not tested were also more likely to believe that people with AIDS must have done something wrong to have AIDS and were more likely to endorse that they would rather not be friends with someone who has AIDS. Finally, individuals who had not been tested were significantly more likely than those who had been tested to have had an STI, and 13% had a history of genital ulcers. Analyses showed that people who were not tested for HIV were more likely to have never used a condom and were more likely to have used injection drugs, both indicating potential higher risk among untested participants. Participants who had been tested were, however, significantly more likely to have been diagnosed with an STI. Taken together, 69% of those who had been tested indicated at least one of seven HIV risk factors (excluding never having used a condom), as did 62% of those who had not been tested, a non-significant difference. Among people who had been tested, those who did not know their test results were significantly more likely to have received and given money or food for sex, suggesting that people involved in sex trade were less likely to know their HIV test results.

**HIV-AIDS prevention knowledge**
Across all participants, AIDS knowledge was generally high; mean score on the knowledge test was 83% correct for the sample (see table 2). However, there was evidence of important misinformation in the context of this relatively high knowledge base. Items that were most frequently answered incorrect were “Must a person have many different partners to get AIDS?” 26%; “Is AIDS caused by spirits or supernatural forces?” 43%; “Does washing after sex help protect against AIDS?” 24%; and “Is there a cure for AIDS?” 24%. Comparisons between individuals who had been and had not been tested for HIV showed that groups did not differ significantly on HIV knowledge test scores, adjusted OR = 0.49, 95% CI = 0.15 to 1.58, and there were no significant group differences on any of the individual knowledge items. There were also no differences between people who knew their HIV test results and people who did not know their results in AIDS knowledge, adjusted OR = 0.95, 95% CI = 0.81 to 1.1.

**Attitudes toward HIV testing**
Comparisons between HIV testing history groups on attitudes towards HIV testing showed that participants who had not been tested held significantly more negative HIV testing attitudes than participants who had been tested after controlling for age, sex, education, and survey venue. Individuals who had not been tested for HIV were significantly less likely to view beneficial outcomes from testing, more likely to perceive adverse testing outcomes, and more likely to endorse test avoidance (see table 3).

Among people who had been tested, individuals who did not know their HIV test results demonstrated significantly more negative attitudes towards testing than those who knew their test results. These findings mirror the results of comparisons between people tested and not tested for HIV. Participants who did not know their test results were less likely to endorse benefits and were more likely to endorse adverse outcomes from testing.

**AIDS stigmas**
Results showed that individuals who had not been tested for HIV held significantly greater AIDS related stigmas than individuals who had been tested. People who had not been tested were significantly more likely to agree that people with AIDS are dirty, should feel ashamed, and should feel guilty. Participants who were not tested were also more likely to believe that people with AIDS must have done something wrong to have AIDS and were more likely to endorse that they would rather not be friends with someone who has AIDS. Finally, individuals who had not been tested were significantly more likely than those who had been tested to have had an STI, and 13% had a history of genital ulcers. Instituted rapid testing with same day results. 17 People who did not know their test results is surprising because South Africa has waited days for test result notification, 16 this high rate of people to not return for their test results when they have to set?lements, especially among those with STIs and genital ulcers, a substantial number of the untested individuals in this study were probably infected with HIV.

More than one in three people who had been tested were not aware of their HIV test results. Although it is common for people to not return for their test results when they have to wait days for test result notification, 16 this high rate of unknown test results is surprising because South Africa has instituted rapid testing with same day results. 17 People who did not know their test results were more likely to have a history of exchanging sex for money or food. In addition, people who did not know their test results held more negative HIV testing attitudes and saw fewer benefits of testing than their counterparts who knew their test results. It is possible that some individuals who stated that they did not know their HIV status had left the testing site before notification of results. It is also possible that some individuals had been notified of their test results but did not understand the meaning of their HIV status. In either case, negative attitudes towards HIV testing may pose barriers to learning one’s HIV test results.

HIV testing history was not associated with AIDS related knowledge, which was generally high in the current sample. Factual based education about HIV transmission is therefore once again found to be necessary but insufficient in promoting HIV antibody testing. 15 In contrast, attitudes toward HIV testing were associated with testing history. Although people who had not been tested held more negative attitudes towards testing than those who had been tested, we still found that two thirds of untested people believed that testing helps them; more than half stated that testing helps prevent HIV, and more than half of people who had not been tested would like to know their HIV status. We therefore conclude that not seeking VCT is more a function of social barriers to getting tested, particularly AIDS stigmas, than a lack of perceived value of getting tested.

AIDS related stigmas create barriers to seeking VCT but not to learning one’s test results. Participants in the current study who were not tested for HIV held significantly more AIDS related stigmatising beliefs than people who had been tested, including negative perceptions of people living with AIDS, a sense that people with AIDS should feel ashamed and guilty, and the endorsement of social sanctions for people living with AIDS. It is important to note that AIDS stigmas were also prevalent among people who had been tested for HIV, although to a lesser degree than among those who had not been tested. These findings are consistent with research in the United States which shows AIDS related stigmas promote and foster social isolation and discrimination against people with HIV-AIDS. 10, 11 Given the history of discrimination experienced by black South Africans, it is not surprising that they would avoid a medical test that potentially adds another source of stigma and discrimination even though apartheid (that is, legalised racial segregation) was abolished almost a decade ago.

Given the prevalence of AIDS stigmas in the black township in Cape Town as reported here, structural interventions are needed to change societal beliefs about people living with AIDS. The knowledge base of HIV prevention information is now high in South Africa, 1 indicating that national efforts to educate the public about AIDS have been successful. However, knowledge appears to only be a necessary precursor to reducing stigma. In the United States, public health laws have been enacted to protect against AIDS discrimination and to protect the confidentiality of an individual’s HIV status. 19 Social marketing campaigns have been effective at raising AIDS awareness and reducing AIDS stigmas. 20 Anti-stigma campaigns have also created positive environments for enacting policies to protect the human rights of people living with HIV-AIDS. 21 Community mobilisation and social activism models can also have broad effects on AIDS stigmas. 22 Efforts to reduce AIDS stigmas are already under way in South Africa through mass media campaigns and public demonstrations and should be sustained to ultimately achieve success. Only through these efforts will AIDS stigma in South Africa be reduced and the goals of VCT realised.

Results of the current study provide new information about factors that potentially influence HIV testing in South Africa. However, there are important limitations to the study that should be considered when interpreting these findings. The study reported here was conducted in one black township in Cape Town, South Africa. Although HIV prevalence in the Western Cape is nearly 11% it is relatively lower than four of the other eight South African provinces. 1 Nearly all of the study participants were African and nearly all lived in poverty. Therefore, caution should be exercised before generalising the study results to other geographic regions and demographic groups. The study also relied on self report measures administered in public venues. Given the high degree of AIDS stigma in South Africa in general, it is likely that the already high rates of risk behaviours observed in the current study are underestimates of actual occurrences. In addition, the study design was cross sectional and therefore does not permit predictive, directional, or causal interpretations of the findings. The HIV testing and risk history measures did not include assessments of time since the behaviours occurred, not allowing us to examine whether people who were recently tested or who recently engaged in risk activities differed from those practising these behaviours less recently. Taking these methodological limitations into account, findings from the current study demonstrate an urgent need for anti-AIDS stigma campaigns and HIV prevention interventions in South Africa. Research is also needed to explore additional barriers to VCT uptake, including attributions of causes of HIV infection, the availability of HIV treatments, and beliefs about HIV treatments.

AIDS stigma and testing in South Africa

Clinical Evidence—Call for contributors

Clinical Evidence is a regularly updated evidence based journal available worldwide both as a paper version and on the internet. Clinical Evidence needs to recruit a number of new contributors. Contributors are health care professionals or epidemiologists with experience in evidence based medicine and the ability to write in a concise and structured way.

Currently, we are interested in finding contributors with an interest in the following clinical areas:

- Altitude sickness; Autism; Basal cell carcinoma; Breast feeding; Carbon monoxide poisoning; Cervical cancer; Cystic fibrosis; Cystic echinococcosis; Grief/bereavement; Halitosis; Hodgkin’s disease; Infectious mononucleosis (glandular fever); Kidney stones; Malignant melanoma (metastatic); Mesoethelioma; Myeloma; Ovarian cyst; Pancreatitis (acute); Pancreatitis (chronic); Polymyalgia rheumatica; Post-partum haemorrhage; Pulmonary embolism; Recurrent miscarriage; Repetitive strain injury; Scoliosis; Seasonal affective disorder; Squint; Systemic lupus erythematosus; Testicular cancer; Vitiligo

Being a contributor involves:

- Appraising the results of literature searches (performed by our Information Specialists) to identify high quality evidence for inclusion in the journal.
- Writing to a highly structured template (about 2000–3000 words), using evidence from selected studies, within 6–8 weeks of receiving the literature search results.
- Working with Clinical Evidence Editors to ensure that the text meets rigorous epidemiological and style standards.
- Updating the text every eight months to incorporate new evidence.
- Expanding the topic to include new questions once every 12–18 months.

If you would like to become a contributor for Clinical Evidence or require more information about what this involves please send your contact details and a copy of your CV, clearly stating the clinical area you are interested in, to Claire Folkes (cfolkes@bmjgroup.com).

Call for peer reviewers

Clinical Evidence also needs to recruit a number of new peer reviewers specifically with an interest in the clinical areas stated above, and also others related to general practice. Peer reviewers are health care professionals or epidemiologists with experience in evidence based medicine. As a peer reviewer you would be asked for your views on the clinical relevance, validity, and accessibility of specific topics within the journal, and their usefulness to the intended audience (international generalists and health care professionals, possibly with limited statistical knowledge). Topics are usually 2000–3000 words in length and we would ask you to review between 2–5 topics per year. The peer review process takes place throughout the year, and our turnaround time for each review is ideally 10–14 days.

If you are interested in becoming a peer reviewer for Clinical Evidence, please complete the peer review questionnaire at www.clinicalevidence.com or contact Claire Folkes (cfolkes@bmjgroup.com).
