CASE REPORT

Localised genital Norwegian scabies in an AIDS patient

A 45 year old Hispanic HIV positive man with an absolute CD4 count of 7 cells x 10⁶/l presented to our clinic in April 2002 with a several months’ history of a pruritic red papular eruption on the abdomen and anterior thighs. The patient had been prescribed lindane topically in two overnight treatments separated by 7 days. Though he used the lindane extensively (over his entire body surface, including the genitalia) and even more frequently (every other night), the infection did not respond. His wife and adult daughter, who lived with him, both reported pruritus without skin lesions. The patient coincidentally noticed an enlarging, non-pruritic, thick, crusted papule on the shaft of his penis that had been growing for roughly 2 months and was 1.6 cm in diameter on the day of presentation (fig 1). A mineral oil preparation from the crusted penile lesion revealed numerous typical mite eggs and scybala, confirming the clinical diagnosis of Norwegian (crusted) scabies. The patient had no acral skin changes and no other areas of thick crusting.

The patient was treated with two doses of oral ivermectin at 200 µg/kg/dose separated by 14 days. The patient received no further topical therapy, but his wife and daughter were given permethrin topical therapy to use overnight in two applications separated by 7 days. The patient returned after 21 days with complete resolution of his skin lesions and pruritus.

DISCUSSION

Norwegian (crusted) scabies most commonly develops in the population of HIV infected patients; however, individuals with other severe immunosuppressive diseases or those who use systemic or topical immunosuppressants are similarly susceptible.1 This is probably because of the inability of the immune system to combat the mites, thereby facilitating an overwhelming reproduction. There is a wide range of presentations of Norwegian scabies in AIDS patients. Lesions range from thick, crusted plaques to red papules to psoriasiform plaques to hyperkeratotic yellow coloured papules resembling Darier’s disease.2 Burrows are characteristic in typical scabies, but may be absent in scabies among AIDS patients.1,3 Pruritus is absent or decreased with Norwegian scabies compared to the intense pruritus characteristic of ordinary scabies.1,3 The lesions in Norwegian scabies are classically distributed on the extremities, but are frequently found on the back, face, scalp, and around the nailfolds.1,3 Our patient’s presentation of pruritic red papules on the abdomen and thighs without burrows was not unusual for an AIDS patient with Sarcoptes scabiei infestation, but the presence of a single thickly hyperkeratotic plaque localised to the glans penis has not yet been reported.

Crusted scabies is particularly difficult to treat because traditional topical therapies do not penetrate sufficiently to eliminate the infection. Attention has turned towards the use of oral ivermectin as a highly effective alternative treatment,4-10 but there remains no definitive consensus on the optimal dosing regimen (including the total number of doses and interval between them) and on the need for concomitant topical therapy.11,12 The majority of reports suggest the use of two doses (200 µg/kg each) given 2 weeks apart. Our patient’s pruritus and all cutaneous lesions resolved completely following administration of this exact regimen and without the necessity for adjunctive topical therapy.
