Circumcision practice in the Philippines: community-based study

Male circumcision is a well studied phenomenon. However, much of the published knowledge on circumcision is derived from highly industrialized Western countries, particularly the United States.1 The non-Western context of circumcision is not well known despite being a universal practice in various countries. For example, in the Philippines, circumcision was common in the past as it is at present, being an integral aspect of the social organisation of the society.2 This report offers a Philippine perspective of male circumcision, particularly its adoption and complications. The study employed semi-structured face to face interviews with 114 circumcised males conveniently recruited using a snowball technique from two communities. One fourth (22) of the clients were aged 13–18, while the rest were older, working in varied and low income occupations, and were single, married, or separated.

The majority of respondents (51.7%) were circumcised between ages 10 and 14. Others had the same experience before age 10 (42.1%) or between 15 and 18 (5.3%). Respondents gave several reasons for their circumcision: not wanting to be called “supot” or uncircumcised (66.7%); being at the right age (41.2%); and wanting to grow tall and physically fit (29.8%). Other reasons included the need to get rid of smegma in the penis (22.8%); to cause pregnancy (20.2%); and to obey parents (18.4%) (table 1). Seven of every 10 clients (68.4%) were circumcised by non-medical providers; the remaining three by medical providers. Respondents paid for their circumcision in cash (51.8%) or in kind (48.2%); more than a third (36%) said that they used the services at no cost but by courtesy of the community and extension services offered by some groups and individuals from or outside their neighbourhood. Six of every 10 respondents (59.6% or 68 of 114) reported having post-circumcision penile complications (inflammation and swelling), while four (40.4%) had none. Almost all (60 of 68) did not consult their circumcisers about their penile complications. The rest (n = 60) self medicated. The healing period was from less than 1 week to 2 months.

Circumcision among the low income respondents occurred at prepubescent ages. Ever since, the procedure has been regarded, along with corollary health reasons, as a rite of passage towards manhood.4 Circumcision was pursued with broad community participation: parents, peers, women, and circumcisers assumed various roles in its adoption. Respondents’ circumcisers included medical doctors and lay people in the community. The central role of lay individuals in undertaking circumcision is part of the traditional character of this community based practice.

Post-circumcision complications were limited to inflammation and swelling, consistent with Western data wherein risks are regarded as minor and complications were at a rate 0.2 to 0.6%.5 Respondents did not take these complications nor the risks from circumcision seriously when they opted not to see their circumcisers and when they adopted self medication. The seeming lack of serious concern for these problems was inappropriate given that the healing period of the circumcised penis of many respondents was highly protracted. Much of the foregoing evidence on reasons for adopting circumcision highlights the fact that respondents’ circumcision was predominantly traditional.

Repeated detection of lymphogranuloma venereum caused by Chlamydia trachomatis L2 in homosexual men in Hamburg

Bacteria of the species Chlamydia trachomatis are divided into serovars that are associated with different disease manifestations. Serovars A-C cause trachoma, which occurs mainly in undeveloped countries. Serovars D-K are responsible for ocular genital infections, and serovars L1, L2, and L3 cause lymphogranuloma venereum (LGV). Infections of serovars A-K are usually confined to the mucosal epithelia of the eyes and the anogenital tract. In contrast, the L-serovars are more invasive and may induce genital ulcer or inguinal lymphadenopathy after passing the epithelial surface.6

While serovars D-K are distributed worldwide and represent the most frequent bacterial sexually transmitted disease in Europe and North America, LGV caused by the L-serovars is a very rare disease in industrialised countries, but is restricted to parts of southeast Asia, Africa, South America, and the Caribbean.7 During the second part of 2003 three patients presented to our clinic with inguinal swellings. In addition, genital ulcer developed in two of them. All patients had homosexual contacts with more than one partner. Two patients were HIV positive, one of them refused HIV testing. The patients assured us that they had not travelled outside Germany during the past year.

In all cases genital C trachomatis infection was diagnosed by DNA amplification in lesional swabs or lymph node aspirates using the SDA technology (ProbeTec ET, Becton-Dickinson, MD). Other infections inducing genital lesions were not detected. None of the patients had a positive serology indicating active infection with Treponema pallidum. Genital infections due to Neisseria gonorrhoeae, Haemophilus ducreyi, and herpes simplex virus were excluded by polymerase chain reaction (PCR) testing. In addition, no genital bacterial and fungal pathogens were detectable by direct microscopy or culture.

After treatment with doxycycline (200 mg per day), genital lesions completely regressed in all patients. Patients 2 and 3 were treated

Determinants of hospital mortality of HIV infected patients from north India

A majority of the HIV infected population lives in developing nations. Most patients require hospitalisation for management of opportunistic infections (OIs) sometime during the course of their illness. Locally endemic infections and underlying malnutrition tend to influence the manifestations and course of the disease. However, there is paucity of data on pattern of disease and determinants of immediate outcome of such patients from Indian subcontinent.

We report the determinants of hospital mortality in a cohort of 135 consecutive cases of HIV/AIDS, aged 13 years and above, admitted to the All India Institute of Medical Sciences (AIIMS), New Delhi, during the period of January 2000 through July 2003. These patients had been hospitalised for suspected OIs, and all patients underwent examination for diagnosis with subsequent management as per standard guidelines. For patients with Pneumocystis jiroveci pneumonia (PCP) whenever hypoxaemia was severe (PaO2<70 mm Hg; n = 5), corticosteroids were given in addition to oral co-trimoxazole. None of these patients required assisted ventilation. Secondary prophylaxis for the OIs was initiated as recommended.

Mean age of the patients was 34 (SD 10) years and 23 patients (17%) were women. CD4+ cell counts were done in 109 patients. Most of these patients (82.6%) had CD4+ cell counts less than 200 cells/mm³. Fifty patients (46%) had CD4+ cell counts less than 50 cells/mm³. The mean number of OI was 4 per patient. The commonest OI was tuberculosis (TB) (71.1%), followed by oral candidiasis (39.3%). Other OIs (full data presented elsewhere) included PCP (n = 10), cryptococcal meningitis (n = 8), cerebral toxoplasmosis (n = 5), cytomegalovirus retinitis (n = 3), visceral leishmaniasis (n = 2), and progressive multifocal leukoencephalopathy (n = 1).

Twenty one patients (15.6%) died in hospital, most of them as a result of TB (n = 16; 76.2%) and PCP (n = 4; 19%). Factors associated with hospital mortality, on bivariate analysis, are shown in Table 1. After adjusting for other factors (by multivariate logistic regression analysis), PCP was the only independent determinant and was associated with a more than fourfold increased risk of hospital mortality (adjusted odds ratio (95% CI): 4.7 (1.1 to 20.9); p = 0.041).

Overall hospital mortality of 15.6% in this cohort is considerable and reflects the advanced nature of the disease at presentation. As our institute is a tertiary care facility for 3 weeks, patient 1 received doxycycline for 1 week only.

The underlying Chlamydia serovars were identified by sequence analysis of omp1 derived DNA fragments amplified using primers MF21 and MB22 as described by Dean et al. In all cases the sequences obtained had highest homology to C. trachomatis serovar L2 but were not identical. While the sequence from patient 1 was shown to be 100% identical to the L2 isolate 434/ Bu over the analysed region of 366 nucleotides, the sequences of patients 2 and 3 were only 89.9% and 99.5% homologous, indicating different sources of infection (Fig 1).

Figure 1 DNA sequence alignment of MOMP-PCR fragments. Nucleotide numbers are according to C. trachomatis strain 434/ Bu (Genbank Acc No M14738). IP, WH, and LL are the initials of the patients who were C. trachomatis positive. Homology to 434/ Bu is 100% (IP), 98.9% (WH), and 99.5% (LL), respectively.

for 3 weeks, while patient 1 received doxycycline for 1 week only.

The underlying Chlamydia serovars were identified by sequence analysis of omp1 derived DNA fragments amplified using primers MF21 and MB22 as described by Dean et al. In all cases the sequences obtained had highest homology to C. trachomatis serovar L2 but were not identical. While the sequence from patient 1 was shown to be 100% identical to the L2 isolate 434/ Bu over the analysed region of 366 nucleotides, the sequences of patients 2 and 3 were only 89.9% and 99.5% homologous, indicating different sources of infection (Fig 1).

Recently, a cluster of 15 LGV cases among homosexual men was reported in Rotterdam. Thirteen of these patients were HIV positive. As with our patients, C. trachomatis serovar L2 was identified in all patients. Although anonymous sexual contacts in Germany were reported, there is yet no epidemiological evidence for a connection of the LGV cases of our study and those reported in Rotterdam.

In conclusion, infections with C. trachomatis serovar L may be more frequent than assumed previously, as indicated by the identification of three different strains in our study. Consequently, LGV should be included in the differential diagnosis of genital ulcer or lymphadenopathy in homosexual HIV infected patients in Europe.

and a national referral centre, this is expected. None the less, it may be possible that some OIs remained undiagnosed and indirectly influenced the outcome. This does occur as was shown in a necropsy study where it was found that a large number of potentially fatal OIs were not diagnosed antemortem.

Unexpectedly, CD4+ counts had no independent effect on mortality. A similar observation has been reported in some previous studies.1 It appears that the virulence of the pathogen causing the OI, rather than the stage of the underlying HIV illness, tends to influence the short term outcome. This finding has important therapeutic implications, especially because almost all these patients die of an OI.

It is suggested that any HIV infected patients with an OI, irrespective of the stage of the disease, should be managed with an aggressive approach. Once they recover from the OI, they can be offered antiretroviral therapy, which, over the years, has become extremely potent and effective. Such an approach is likely to improve the long term outcome of these patients.

Refrigeration does not compromise recovery of Neisseria gonorrhoeae from charcoal transport swabs

Despite emergent molecular diagnostics, cultural recovery of Neisseria gonorrhoeae (NG) remains important for the diagnosis of gonorrhoea, as well as for susceptibility and epidemiological study. Although inoculation of bacteriological media in clinic is optimal, it can prove impractical, or impossible, in some healthcare settings. Further, any healthcare strategy that distances patient testing from diagnostic laboratories reinforces the need for transport media.

Many users assume that commercial transport systems offer comparable performance characteristics, so could choose mass mode choice. However, a proposed NCCLS standard for transport media (M40)1 is likely to confirm significant variations in performance both between different manufacturers’ products. Similarly, little attention has been given to the storage temperature for swabs after use; textbooks offer conflicting recommendations. Overgrowth and killing of NG in transport media by contaminating bacteria may be inhibited by refrigeration, but it is unclear whether refrigeration is detrimental to recovery of NG.
To address this we compared the survival of 30 distinguishable clinical strains of NG in charcoal transport swabs held at ambient temperature (AT: 20–22°C) and at 4°C.

Swabs (Transwab: Medical Wire & Equipment Co) were inoculated with a suspension of NG in phosphate buffered saline (PBS). For each strain, four swabs were inoculated, to allow comparison of storage at AT or 4°C, for 24 or 48 hours. At 48 hours and 48 hours, NG organisms were successively potentiating swabs by vortexing the tips in 1 ml PBS. Triplicate counts were performed on the 0 hour inocula and the washings on chocolate agar (Oxoid, Basingstoke, UK) using a spiral plater (Don Whitley, Shipley, UK). The median value for each triplicate was taken, and counts compared using the Wilcoxon rank sum test.

At 24 hours there was no significant difference between AT and 4°C counts, with median (interquartile range, IQR) recoverable 

\[ \text{log}_{10} \text{CFU} = 4.57 \text{ (3.78–4.84) and 4.72 \text{ (4.32–4.87), respectively (fig 1). At 24 hours one strain held at AT was not recovered (see fig 1). At 48 hours, six strains held at AT and three at 4°C were not recovered; median counts (IQR) were 3.09 \text{ (1.3–3.55) and 3.855 \text{ (3.19–4.53) for AT and 4°C, respectively (p = 0.004).}} \]

Sng et al in a semiquantitative study tested five strains in Amies medium at four temperatures (4, 18, 26, and 32°C) and found five strains in Amies medium at four temperatures better recovery at 4°C.

Control strains of NG have usually shown prolonged survival. Studies using laboratory cultures have demonstrated better survival at lower temperatures.

The median value for the AT group was 3.26 (2.01–4.53) for AT and 4°C, respectively.

To address this we compared the survival of 30 distinguishable clinical strains of NG in charcoal transport swabs held at ambient temperature or 4°C. *NR, none recovered (p < 0.82).

**Prevalence of chlamydial infection was 9.5% (10.4% in men, 9.0% in women). Somewhat to our surprise, the 15–19 year old age group showed peak prevalence in men as well in women.**

We compared this with the prevalence by age in men attending Edinburgh GUM (see table 1), anticipating this would be highest in the 20–24 year old age group. Although this was the case for 2002, in 2003 the peak prevalence was in 15–19 year olds, with the proportion of all positive tests in men as a result of the under 20s increasing significantly from 10.1% (51/504) in 2002 to 14.8% (74/500) in 2003 (χ² = 5.05; p = 0.025).

**There is no doubt that in men, the age group 20–24 accounts for the highest number of cases diagnosed, but our data raise the possibility that either there has been underdiagnosis of cases in younger men or that there is a trend towards younger transmission. Although we only report on 2 years' data, it will be essential to monitor emerging trends by concentrating efforts to include teenage men in chlamydia testing programmes.**

**Chlamydia in heterosexual men: could peak prevalence be in teenagers?**

The CMO’s expert advisory group on *Chlamydia trachomatis* and the Health Protection Agency (HPA) both state that rates of chlamydial infection are highest among 16–19 year old females and 20–24 year old males. Staff based in the genitourinary medicine (GUM) department in Edinburgh have set up a number of community-based initiatives, including a postal testing service, to improve access to chlamydia diagnosis for young people aged less than 25. Many of these initiatives have been targeted specifically at young men, with testing having been made available in a variety of novel settings such as young people’s sexual health and drop-in clinics, further education (FE) colleges, community pharmacies, sports centres, and a high street shop selling CDs. The works forms part of a demonstration project called Healthy Respect that is funded by the Scottish Executive with the aim of helping young people to in Lothian to develop a positive attitude towards their own sexuality and that of others. The long term goal of the project is to reduce teenage pregnancies and sexually transmitted infections. Between February 2002 and December 2003, as part of the Healthy Respect project, we carried out 4838 chlamydia tests including 2321 from postal testing kits. The overall prevalence of chlamydial infection was 9.5% (10.4% in men, 9.0% in women). Somewhat to our surprise, the 15–19 year old age group showed peak prevalence in men as well in women.

We compared this with the prevalence by age in men attending Edinburgh GUM (see table 1), anticipating this would be highest in the 20–24 year old age group. Although this was the case for 2002, in 2003 the peak prevalence was in 15–19 year olds, with the proportion of all positive tests in men as a result of the under 20s increasing significantly from 10.1% (51/504) in 2002 to 14.8% (74/500) in 2003 (χ² = 5.05; p = 0.025).

There is no doubt that in men, the age group 20–24 accounts for the highest number of cases diagnosed, but our data raise the possibility that either there has been underdiagnosis of cases in younger men or that there is a trend towards younger transmission. Although we only report on 2 years’ data, it will be essential to monitor emerging trends by concentrating efforts to include teenage men in chlamydia testing programmes.
