Background When sexual partners have risky context characteristics (i.e., partner drinking alcohol within two hours before sex, > 3 age discordant, or met in public), adolescents are particularly vulnerable to having unprotected sex and acquiring sexually transmitted diseases. Based on social cognitive theory, we assessed the influence of adolescents’ alcohol use, their friends’ ages and alcohol use, and parental monitoring on adolescent sexual partner selection to identify potent predictive factors.

Methods Data were from an urban cohort of youth participating in the Project Northland Chicago group-randomised, alcohol prevention intervention trial. We used ordinal logistic regression to analyse the predictive effect of 8th grade self, peers, and parents factors on a sexual partner context risk score of 0 to 3 with 1 point for each risk characteristic of 17–18 year olds most recent sex partner. We adjusted analyses for sexual partner relationship characteristics (casual or unexpected).

Results Women were more likely to choose risky context partners at ages 17–18 years old if in 8th grade they had older friends (Odds Ratio (OR) = 1.5, 95% Confidence Interval (CI) = 1.1 to 2.1) or reported risky alcohol use behaviours (OR = 1.9, 95% CI = 1.2 to 1.9). Men were more likely to choose risky context partners at ages 17–18 years old if in 8th grade their friends were drinking alcohol (OR = 1.3, 95% CI = 1.0 to 1.7). Parental monitoring did not influence partner selection.

Conclusions Peers and alcohol use influence adolescents’ selection of risky context partners. For alcohol, self-use appears more important among women, and friends’ use appears more important among men. Interventions to reduce sexual risk-taking and risky partner selection among adolescents should target friends and alcohol use.

Background In Mexico, the HIV estimated prevalence among men with sex (MSM) is 17%, being the sexual transmission the most important via (90%). In other countries, studies report that almost 43% of MSM with HIV (MSM-H) have unsafe use. Use of alcohol, substances, misinformation of HIV transmission, perceived low-risk of infection, self-stigma, and others, are related to this type of sexual behaviour. Self-stigma in MSM-H who have unsafe sex has been poorly studied, and had contradictory results.

Methods Over 2012, after the ethical requirements, we asked MSM-H about unsafe sex with the Behavioral Surveillance Survey for MSM of 2006, and self-stigma with the HIV/AIDS Stigma Instrument—PILWA (HASI-P). This study was conducted at the Condesa Specialized Clinic in Mexico City, which is the largest Latin American clinic for people with HIV. We determine unsafe sex dichotomously if the participant had not used condom, or had used non-water soluble lubricants during anal sex. We observed that self-stigma score had a non-normal distribution, so we used the Wilcoxon-Mann-Whitney test to compare it between the two groups.

Results The total sample was 200 MSM-H, and the mean age was 38.6 (S.D., 8.3) years old, and the level of education was 12.9 (S.D., 3.1) years (high-school equivalent). The 52.5% of the sample had unsafe sex and the median score of self-stigma was 6 (range: 0–28) points. After comparative analysis we didn’t find any significant differences of self-stigma between the two groups (p = 0.25).

Conclusion The self-stigma among MSM-H is not a factor related to unsafe sex, because this behaviour involves other social factors that must be deeply studied, particularly in this population. We have to include in future studies factors such as impulsivity, mental disorders, use of alcohol or substances, or others aspects that could probably be related to this behaviour.
‘sexting’ as key term. We extracted data on; reasons for sexting, attitudes, and factors statistically associated with sexting.

**Results** Seven studies were included, most were cross-sectional, all were quantitative and conducted in the United States. Six studies assessed correlates of sexting in teenagers/young adults and found the following statistical associations; older adolescent, dating, sexually active, sexual risk behaviours, substance use, lower parental educational, peers sexting, and greater texting frequency. Girls were more likely to be senders, boys more likely to be receivers and to have asked someone to sext. Sexually active respondents were more likely to be both senders and receivers. Two studies explored attitudes about sexting finding those who sent pictures were more likely to consider sexting acceptable, over one third of non-sexers reported positive attitudes towards sexting, and most of those who sent pictures were bothered by having been asked to sext. Expecting serious legal consequences for getting caught sexting did not reduce reported sexting.

**Conclusion** Many young people don’t perceive sexting negatively. Sexting may either be part of a cluster of risky sexual behaviours or in fact lead to sexual risk behaviour. Because of the cross-sectional nature of the studies, we were unable to determine causality. Additional research is needed to understand contexts in which sexting occurs, and motivations. Longitudinal designs are required to explore causality with sexual risk behaviour.

**P4.079** SEXUAL BEHAVIORS AND SAFETY STRATEGIES OF WOMEN WHO HAVE SEX WITH MEN AND WOMEN

V R Schick, A Bell, C Neal, B Van Der Pol, B Dodge, L Bay-Cheng, J D Fortenberry, J Indiana University, Bloomington, IN, United States; 2University at Buffalo, Buffalo, NY, United States; 3Indiana University, Indianapolis, IN, United States

**Background** Women who have sex with women and men (WSWM) are at an increased risk for STI. Yet, knowledge regarding the behaviours associated with infection remains limited, with most studies focused on the experiences of women who have sex with only men or women. The diversity of sexual behaviours WSWM engage in may be limited by comparing WSWM to other groups. Instead, focusing on their experiences exclusively may provide a more comprehensive understanding of the sexual lives of WSWM.

**Methods** Local (Indianapolis, IN, US) women who had engaged in recent genital contact with a male and female partner were invited to complete an online survey followed by an interview. Participants were asked to indicate the most recent time they had participated in a variety of behaviours with a male and/or female partner.

**Results** Eighty participants ranging in age from 18 to 51 (M = 26.74, SD = 7.97) completed the survey. The most commonly reported sexual behaviours were similar for male and female partners, including kissing, cuddling, external genital rubbing, vaginal fingering, cunnilingus/fellatio and penile-vaginal intercourse. While less commonly reported, a sizable minority of participants reported vaginal stimul, anal fingering and analusis. Toy use was reported by the majority of the participants with vibrator use reported as the most commonly used toy. Approximately 75% of participants indicated sexual behaviour with more than one person at one time. The percentage of participants who reported barrier use varied by behaviour and partner gender with the lowest percentage of participants reporting use during oral sex or genital-on-genital rubbing with a female partner (> 90% never) and the highest percentage reporting use during penile-vaginal intercourse (> 25% always).

**Conclusion** Participants reported engaging in a variety of sexual behaviours that may facilitate STI transmission. Further knowledge about the types of behaviours WSWM engage in may help inform risk reduction strategies.

**P4.080** UNDERSTANDING THE INFLUENCE OF INDIVIDUAL AND PARTNER-SPECIFIC SEXUAL SEALTH ON SEXUAL RISK BEHAVIOUR AMONG ADOLESCENT WOMEN

D J Hensel, J Fortenberry. Indiana University School of Medicine, Indianapolis, IN, United States

**Background** Sexual health identifies both individual and partner-specific factors as important elements in public health approaches to STI prevention among adolescents, yet little empirical evidence links them to specific STI-related health outcomes.

**Method** Data were individual and partner-specific quarterly interviews from a cohort of young women in Indianapolis (N = 387, 14–17 yrs.). Using an existing sexual health definition (WHO, 2002) we created two standardized, multi-item sexual health scales: individual sexual health (sexual positiveitv, absence of genital pain, family communication, family connection) and partner-specific sexual health (relationship satisfaction, sexual satisfaction, condom use self-efficacy, pregnancy prevention attitudes, sexual communication, partner’s connection to family) (both α ≥ 0.85). Outcomes were: used a condom at last sex (no/yes), ratio of condom-protected coital events, any sexual coercion (no/yes), current number sex partners (2+/1), future number of sex partners (next 90-days: 2+/1). Analyses were multi-level logistic and linear regression (HLM, 7.0; all p < 0.05), overall and by current number of sexual partners.

**Results** Individual (OR = 1.22) and partner-specific (OR = 1.87) sexual health predicted condom use at last sex; partner-specific sexual health predicted no sexual coercion (OR = 0.69), a higher ratio of condom-protected coital events (b = 0.12), as well as having one sexual partner currently and for the anticipated future. Higher partner-specific sexual health predicted condom use at last sex in currently single (OR = 1.70) and in currently multiple partner relationships (OR = 2.22), a higher ratio of condom protected coital events in currently single (b = 0.15) and in currently multiple partner relationships (b = 3.66), and absence of sexual coercion (OR = 0.19) in currently multiple-partner relationships.

**Conclusion** Individual and partner-specific sexual health are separately linked to key STI-related public health indicators. These data suggest that different elements may require emphasis to more fully support effective sexual health approaches to reducing STI in adolescents.

**P4.081** STD RISK PERCEPTION AMONG HIGHER RISK UNIVERSITY STUDENTS IN HALIFAX, CANADA

D B Langille, A Steenbeek. Dalhousie University, Halifax, NS, Canada

**Background** Perceived risk is central to health behaviour theory, though little is known about what creates perceived risk of contracting STIDS. We examined self-rated risk of STD in higher sexual risk (HSR) university students in Halifax, Canada, to determine factors associated with recognition of such risk status.

**Methods** Using an online survey, we asked university students about their perception of their STD risk (greatly/quite a lot at risk versus not very much/no risk), their sexual behaviours, chlamydia knowledge (CK), friends’ more liberal attitudes to sexual risk-taking (FLASRT), depression, and personal factors. HSR was defined as having had both ≥ 2 partners for vaginal sex in the past year and no condom use at last intercourse. Variables initially associated with perceived HSR (p < 0.10) were entered into a logistic regression model controlling for gender to determine which remained associated with perception of being at HSR.

**Results** The survey response rate was 32% (N = 4490), and 526 were at HSR. Of those with 2–5 partners in the previous year, only 14% rated themselves as at HSR, while 43% of those with ≥ 6
